Abstract

We investigate a network design problem under traffic uncertainty which arises when provisioning Virtual Private Networks (VPNs): given a set of terminals that must communicate with one another, and a set of possible traffic matrices, sufficient capacity has to be reserved on the links of the large underlying public network so as to support all possible traffic matrices while minimizing the total reservation cost. The problem admits several variants depending on the desired topology of the reserved links, and the nature of the traffic data uncertainty. We present compact linear mixed-integer programming formulations for the problem with the classical hose traffic model and for a new, less conservative, robust variant relying on the traffic statistics that are often available. These flow-based formulations allow to solve optimally medium-to-large-size instances with commercial MIP solvers. We also propose a combined branch-and-price and cutting plane algorithm to tackle larger instances. Computational results obtained for several classes of instances are reported and discussed.

Key words: Virtual private networks, network design, traffic uncertainty, robust optimization, linear mixed-integer programs, branch-and-price, cutting planes.

1 Introduction

Virtual Private Networks (VPNs) are IP-based networks that use encryption and tunneling to link branch offices to an enterprise network, or to extend organizations' existing computing infrastructure to include partners, suppliers and customers [11]. The use of public networks reduces operational costs due to economies of scale while ensuring a wider area accessibility and communication security through encryption. Flexibility and cost effectiveness have turned VPN solutions into a billion dollar industry.

In this paper we address a network design problem that arises when provisioning VPNs. Given a set of terminals that must communicate with one another and a set of possible traffic patterns, sufficient capacity has to be reserved on the links of the large underlying public network so as to support all possible traffic patterns while minimizing cost. The solution of this resource management problem clearly depends on the possible traffic patterns and the constraints on the topology of the reserved links.

In traditional network design problems, it is assumed that a traffic matrix, i.e., a set of demands for all origin-destination pairs, can be reliably estimated. Since a VPN service customer has in general no precise information about the expected traffic between the terminals to be connected, a collection of possible traffic matrices have to be simultaneously considered. In [12] a flexible model was proposed to specify the bandwidth requirements of a single VPN. In this *hose model*, the set of *valid* traffic matrices is defined by imposing, for each terminal t, an upper bound on the total outgoing traffic from t (towards the other terminals) and an upper bound on the total entering traffic in t (from the other terminals).

*Research supported through grant MISAG-CNR-1 jointly from TUBITAK, The Scientific and Technological Research Institution of Turkey, and CNR, Consiglio Nazionale delle Ricerche, Italy.

The underlying network over which a VPN has to be provisioned is represented by an undirected graph $G = (V, E)$. Each edge e in E, also denoted by $\{i, j\}$ to emphasize the two end-nodes i, j in V, has a per-unit non-negative reservation cost c_e. Let $Q \subseteq V$ denote the set of terminals that need to communicate with one another. For each ordered pair of terminals (s, t), with $s, t \in Q$, d_{st} represents the amount of traffic that has to be routed from s to t. Clearly $d_{st} \geq 0$ for every pair of terminals $s, t \in S$. We assume that $d_{ss} = 0$ for every terminal s and denote by S the set of all ordered pairs of terminals requiring traffic, namely $S = \{(s, t) \in Q \times Q : d_{st} > 0\}$. In the hose model, two non-negative bounds b_s^+ and b_s^- are specified for each terminal s in Q and the demands d_{st} must satisfy the following constraints:

$$\sum_{t:t\neq s} d_{st} \leq b_s^+, \quad \sum_{t:t\neq s} d_{ts} \leq b_s^- \qquad \forall s \in Q \tag{1}$$

$$d_{st} \geq 0 \quad \forall (s, t) \in S. \tag{2}$$

Throughout this paper we make the realistic assumption that traffic is *unsplittable*[1], i.e., for each demand pair $(s, t) \in S$ the traffic demand d_{st} is routed along a *single path* from s to t. Provisioning a VPN then consists in reserving capacity on the edges and selecting a single routing path for each demand pair so as to support all valid traffic matrices while minimizing the total reservation cost. This network design problem, which has a multicommodity flow structure, is both continuous and discrete in nature since fractional amounts of capacity can be reserved on the links and demands must be routed along single paths.

If no particular constraint is imposed on the topology of the reserved network (union of all edges with a strictly positive capacity reservation), the VPN provisioning problem with the hose traffic model is called *Asym-G*. The version in which the reserved network is required to be a tree is referred to as *Asym-T*. If the traffic matrix $D = (d_{st})_{s,t\in Q}$ is assumed to be symmetric ($d_{st} = d_{ts}$ for all pairs of terminals s, t) and $b_s^+ = b_s^-$, for all terminals $s \in Q$, the variants are referred as *Sym-G* and *Sym-T*, respectively. Note that in the symmetric case the above assumptions imply the following constraints on the demands:

$$\sum_{t:t>s} d_{st} + \sum_{t:t<s} d_{ts} \leq b_s \qquad \forall s \in Q \tag{3}$$

$$d_{st} \geq 0 \quad \forall (s, t) \in S, \tag{4}$$

with upper bounds on the cumulative entering and outgoing traffic.

To the best of our knowledge, the state-of-the-art on the computational complexity of these variants can be summarized as follows:

- *Sym-T* can be solved in polynomial time by shortest path computations [16];
- *Asym-T* is strongly NP-hard and does not admit a polynomial time approximation scheme, unless $\mathcal{P} = \mathcal{NP}$ [16], and the best known approximation algorithm is guaranteed to yield a VPN whose total reservation cost is at most 9 times larger than that of a minimum cost VPN [19];
- Any optimal solution for *Sym-T* provides a 2-approximation to *Sym-G* [16] but it is still open whether *Sym-G* is actually NP-hard;
- The best approximation algorithm for *Asym-G* has a 5.55 factor [18] but it is still open whether also *Asym-G* is actually NP-hard.

In the present paper we develop new, compact, linear mixed-integer programming (MIP) formulations for the *Asym-G* and *Sym-G* variants of the VPN provisioning problem under the hose model of uncertainty (cf. Proposition 1). Although the computational complexity status of *Asym G* is still open, medium to large instances of our models turn out to be solvable by off-the-shelf mixed integer optimizer Cplex 8.1 within short computing time.

[1]Although the case where each traffic demand can be arbitrarily split and routed along several paths is considered among others in [10], multi-path routing is currently hardly implementable in VPNs because packets related to a single flow may arrive out of sequence and thus cause critical problems at the Transfer Control Protocol (TCP) level.

Traffic uncertainty is a crucial feature in VPN provisioning. Since the hose model makes very weak assumptions (only imposes upper bounds on the inflow and outflow of each terminal), it may lead to excessive capacity reservation. This traffic model is a special case of the so-called *polyhedral model* in which the set of valid matrices is defined by an arbitrary polyhedron [15]. In principle the polyhedral model allows to focus on smaller subsets of traffic matrices than the hose model, but it is unclear how to actually define realistic polyhedra that would lead to less conservative VPN reservations.

From the application point of view, a service provider simultaneously provisions a number of VPNs for different customers over a certain time period and the service level agreements are re-negotiated on a regular basis. While the hose traffic model is adequate for new VPNs in the absence of precise traffic predictions, it is clearly overly conservative for VPNs that are already provisioned. Since service providers collect detailed terminal-to-terminal traffic statistics for each VPN, a less conservative traffic uncertainty model which exploits the available statistics is needed. Therefore, we propose a less conservative robust variant of the problem, which exploits the traffic statistics that are available for existing VPNs, and a corresponding compact linear MIP formulation (cf. Proposition 2); the associated combinatorial problem is shown to be NP-hard (cf. Proposition 3).

In practice, service providers face an incremental reservation problem: while provisioning a given set of VPNs, they receive a request for a new VPN or for changes to the set of terminals of an existing one. Since the additional capacity requirements for a single VPN are in general very small compared with the overall network capacity, it is reasonable from an application point of view to focus on the uncapacitated versions of the VPN provisioning problem [7]. Due to the absence of capacity constraints and the fractional capacity that can be reserved on each link of the backbone network, the incremental problem can then be decomposed into a sequence of single VPN provisioning problems with appropriate traffic uncertainty models.

The rest of the paper is organized as follows. In Section 2 we present compact flow-based linear MIP formulations for the asymmetric and symmetric versions of the VPN provisioning problem with the hose traffic model. In Section 3 we propose the less conservative robust variant of the problem and a corresponding compact linear MIP formulation. In Section 4 we describe path and cut formulations and a combined branch-and-price and cutting plane algorithm to tackle larger instances of the three problem versions. Computational results obtained for several classes of instances are reported and discussed in Section 5. Section 6 contains some concluding remarks.

2 VPN provisioning problem with the hose traffic model

For new VPNs or existing ones in which at least a new terminal is added, demand statistics are not available or not reliable due to the lack of information about the traffic generated by the new terminals. The hose uncertainty model is then well suited for the demands involving at least a new terminal.

Consider the general variant *Asym-G* with asymmetric traffic matrices. Let c_{ij} denote the cost of reserving a unit of capacity on edge $\{i,j\}$. The network cost, which depends on the capacity to be reserved so as to route all demands, has to be minimized. Since traffic is assumed to be *unsplittable*, each demand has to be routed along a single path from origin to destination.

2.1 From constant traffic matrices to the hose model

Let us first consider the capacity reservation problem aiming at minimizing cost while supporting a single traffic matrix $D = (d_{st})_{s,t \in Q}$ and note that a straightforward minimum cost flow formulation can be solved in polynomial time. We define two classes of variables. For each oriented arc (i,j), the continuous variable x_{ij} represents the capacity to be reserved on edge $\{i,j\}$. Let $A = \{(i,j) : \{i,j\} \in E\}$ denote the underlying set of oriented arcs. For each oriented arc $(i,j) \in A$ and oriented pair of terminals $(s,t) \in S$, the binary variable y_{ij}^{st} corresponds to the flow on the oriented arc (i,j) for the terminal pair (s,t)

$$y_{ij}^{st} = \begin{cases} 1 & \text{if arc } (i,j) \text{ is used to route demand } d_{st} \\ 0 & \text{otherwise.} \end{cases}$$

This leads to the flow formulation:

$$\min \quad \sum_{\{i,j\}\in E} c_{ij}x_{ij} \tag{5}$$

$$\text{s.t.} \quad \sum_{j:\{i,j\}\in E} \left(y_{ij}^{st} - y_{ji}^{st}\right) = \begin{cases} 1 & i = s \\ -1 & i = t \\ 0 & \text{otherwise} \end{cases} \qquad \forall i \in V,\ \forall (s,t) \in S \tag{6}$$

$$\sum_{(s,t)\in S} d_{st}(y_{ij}^{st} + y_{ji}^{st}) \leq x_{ij} \qquad \forall \{i,j\} \in E \tag{7}$$

$$y_{ij}^{st} \in \{0,1\} \qquad \forall \{i,j\} \in E,\ \forall (s,t) \in S \tag{8}$$

$$x_{ij} \geq 0 \qquad \forall \{i,j\} \in E, \tag{9}$$

where the objective function corresponds to the VPN reservation cost. Constraints (6) ensure demand satisfaction by imposing a unit flow between each oriented pair of terminals. For each edge $\{i,j\}$ the corresponding constraint (7) guarantees that the capacity x_{ij} reserved on $\{i,j\}$ is sufficient to carry the total traffic flowing through it.

If all the demands d_{st} are precisely known, (5)-(9) is a linear mixed-integer program. Due to the non-negativity of the costs c_{ij} and of all variables, the continuous variables x_{ij} can be omitted and we have the equivalent formulation:

$$\min \quad \sum_{\{i,j\}\in E} c_{ij} \sum_{(s,t)\in S} d_{st}(y_{ij}^{st} + y_{ji}^{st}) \tag{10}$$

$$\text{s.t.} \quad \sum_{j:\{i,j\}\in E} \left(y_{ij}^{st} - y_{ji}^{st}\right) = \begin{cases} 1 & i = s \\ -1 & i = t \\ 0 & \text{otherwise} \end{cases} \qquad \forall i \in V,\ \forall (s,t) \in S \tag{11}$$

$$y_{ij}^{st} \in \{0,1\} \qquad \forall \{i,j\} \in E,\ \forall (s,t) \in S \tag{12}$$

with only binary variables. Since there are no capacity constraints and fractional capacities can be reserved on the edges, the constraint matrix is totally unimodular and the problem is solvable in polynomial time [17].

If the traffic matrix D is subject to the hose uncertainty model, a first formulation is obtained by adding constraints (1)-(2), or respectively (3)-(4), to the nominal problem formulation (5)-(9). These traffic constraints define the so-called demand polyhedron, that is the set of all valid traffic matrices to be supported. Note that the resulting MIP is non-linear due to the bilinear constraints (7). According to (10)-(12), when the traffic demands are uncertain the problem can be seen as a binary integer program in which the only uncertain parameters are the objective function coefficients.

Two previous works [10, 15] deal with this non-linearity by dynamically generating a set of traffic matrices corresponding to vertices of the demand polyhedron. Solving a linearized partial formulation yields values for the flow variables $\tilde{y}_{ij}^{st}$ and the capacity variables $\tilde{x}_{ij}$. Since the resulting routing vector $\tilde{\mathbf{y}}$ may be infeasible for the hose polyhedron defined by constraints (1)-(2), or by (3)-(4), a new vertex (traffic matrix) is sought by solving another linear program, where the $\tilde{y}$'s and $\tilde{x}$'s are considered as coefficients and the edge overload $\sum_{(s,t)\in S} d_{st}(\tilde{y}_{ij}^{st} + \tilde{y}_{ji}^{st}) - \tilde{x}_{ij}$ is maximized over this polyhedron. If there exists a valid traffic matrix $(\check{d}_{st})_{s,t\in Q}$ that is not supported by the capacity $\tilde{x}_{ij}$ reserved on edge $\{i,j\}$, i.e., if such overload is positive, a new constraint (7) with coefficients $\check{d}_{st}$ is added to the formulation. If no such traffic matrix is found for any edge $\{i,j\}$, the reserved capacities support all valid traffic matrices. Thus these row-generation algorithms repeatedly improve a dual bound until primal feasibility is reached. Although the focus is on critical demand values, $|E|$ linear programs must be solved at each iteration. In the special case of the hose model, these linear programs reduce to min-cost-flow problems, which yield an integral maximum flow on each edge [15]. In [15] computational results are reported for a special class of instances with unbounded entering traffic in each terminal. In [10] the authors consider multiple-path routing and check the validity of a reservation vector over a demand polyhedron with integral vertices. To the best of our knowledge, this does not actually imply that such a reservation vector supports all valid traffic matrices with fractional demands when single-path routing is considered. Examples where a reservation vector that is

feasible for all valid integral traffic matrices does not support some valid fractional ones, can indeed be easily found.

2.2 A compact linear MIP formulation for the problem with hose model

Unlike in the above-mentioned works, we simultaneously consider all demand constraints and derive a compact linear MIP formulation.

Proposition 1 *The Asym-G problem is equivalent to the following linear mixed-integer program:*

$$\min \quad \sum_{\{i,j\}\in E} c_{ij}x_{ij} \tag{13}$$

$$\text{s.t.} \quad \sum_{j:\{i,j\}\in E} \left(y_{ij}^{st} - y_{ji}^{st}\right) = \begin{cases} 1 & i = s \\ -1 & i = t \\ 0 & \text{otherwise} \end{cases} \qquad \forall i \in V,\ \forall (s,t) \in S \tag{14}$$

$$\sum_{s\in Q} (b_s^+ \omega_{ij}^{s+} + b_s^- \omega_{ij}^{s-}) \le x_{ij} \qquad \forall \{i,j\} \in E \tag{15}$$

$$\omega_{ij}^{s+} + \omega_{ij}^{t-} \ge (y_{ij}^{st} + y_{ji}^{st}) \qquad \forall \{i,j\} \in E,\ \forall (s,t) \in S \tag{16}$$

$$y_{ij}^{st} \in \{0,1\} \qquad \forall \{i,j\} \in E,\ \forall (s,t) \in S \tag{17}$$

$$\omega_{ij}^{s+},\ \omega_{ij}^{s-},\ x_{ij} \ge 0 \qquad \forall \{i,j\} \in E,\ \forall s \in Q. \tag{18}$$

Proof: Start from the non-linear flow formulation for *Asym-G*:

$$\min \quad \sum_{\{i,j\}\in E} c_{ij}x_{ij} \tag{19}$$

$$\text{s.t.} \quad \sum_{j:\{i,j\}\in E} \left(y_{ij}^{st} - y_{ji}^{st}\right) = \begin{cases} 1 & i = s \\ -1 & i = t \\ 0 & \text{otherwise} \end{cases} \qquad \forall i \in V,\ \forall (s,t) \in S \tag{20}$$

$$\sum_{(s,t)\in S} d_{st}(y_{ij}^{st} + y_{ji}^{st}) \le x_{ij} \qquad \forall \{i,j\} \in E \tag{21}$$

$$\textstyle\sum_{t\ne s} d_{st} \le b_s^+,\ \sum_{t\ne s} d_{ts} \le b_s^- \qquad \forall s \in Q \tag{22}$$

$$d_{st} \ge 0 \qquad \forall (s,t) \in S \tag{23}$$

$$y_{ij}^{st} \in \{0,1\} \qquad \forall \{i,j\} \in E,\ \forall (s,t) \in S \tag{24}$$

$$x_{ij} \ge 0 \qquad \forall \{i,j\} \in E. \tag{25}$$

Consider a single edge $\{i,j\}$ and treat the y's variables as parameters. The worst-case value for the capacity x_{ij} to be reserved on edge $\{i,j\}$ is obtained by solving the following optimization problem:

$$x_{ij} \ge \quad \max \sum_{(s,t)\in S} d_{st}(y_{ij}^{st} + y_{ji}^{st}) \tag{26}$$

$$(\omega_{ij}^{s+}) \qquad \sum_{t\ne s} d_{st} \le b_s^+ \qquad \forall s \in Q \tag{27}$$

$$(\omega_{ij}^{s-}) \qquad \sum_{t\ne s} d_{ts} \le b_s^- \qquad \forall s \in Q \tag{28}$$

$$d_{st} \ge 0 \qquad \forall (s,t) \in S, \tag{29}$$

where the ω's are the corresponding dual variables. Since this linear program is feasible and bounded, strong duality yields the equivalent formulation:

$$x_{ij} \geq \min \sum_{s \in Q} (b_s^+ \omega_{ij}^{s+} + b_s^- \omega_{ij}^{s-}) \tag{30}$$

$$\omega_{ij}^{s+} + \omega_{ij}^{t-} \geq y_{ij}^{st} + y_{ji}^{st} \qquad \forall (s,t) \in S \tag{31}$$

$$\omega_{ij}^{s+},\ \omega_{ij}^{s-} \geq 0 \qquad \forall \{i,j\} \in E,\ \forall s \in Q. \tag{32}$$

By replacing constraints (26)-(29) with (30)-(32), we eliminate the non-linearity implied by demand uncertainty and obtain a lower bound on the capacity that is required on edge $\{i,j\}$. This substitution immediately leads from (19)-(25) to the linear MIP formulation (13)-(18). ∎

Analogously, for the *Sym-G* case we obtain a compact formulation with the same objective function (13), the flow conservation constraint (14) and

$$\sum_{s \in Q} b_s \omega_{ij}^s \leq x_{ij} \qquad \forall \{i,j\} \in E \tag{33}$$

$$\omega_{ij}^s + \omega_{ij}^t \geq y_{ij}^{st} + y_{ji}^{st} \quad \forall (s,t) \in S \tag{34}$$

$$\omega_{ij}^s \geq 0 \qquad \forall \{i,j\} \in E,\ \forall s \in Q. \tag{35}$$

As we shall see in Section 5, tackling this compact linear MIP formulation with commercial solvers (e.g., Cplex 8.1) yields optimal solutions even for large-size instances.

3 Robust VPN provisioning problem

Since detailed traffic statistics (reliable average and standard deviation estimates of terminal-to-terminal traffic) are available for existing VPNs, we consider a variant of the VPN provisioning problem which exploits this additional information. Unlike in the hose model, where bounds are imposed on the aggregated traffic through each terminal, we adopt a less conservative traffic uncertainty model and consider each demand d_{st} individually. However, our assumptions regarding the valid traffic matrices are very mild: we just assume that we know the range of values that each demand d_{st} can take. Specifically, for each pair of terminals $s,t \in Q$, the demand d_{st} is assumed to take values in an interval $[d'_{st} - \hat{d}_{st}, d'_{st} + \hat{d}_{st}]$, where $\hat{d}_{st}$ denotes the positive deviation from the nominal value d'_{st}. It is worth emphasizing that we do not make any assumptions concerning the distribution of the traffic demands within the corresponding intervals and concerning the way different demands d_{st} may be interrelated.

For non-negative deviations $\hat{d}_{st}$, the robust VPN provisioning problem in which the demands are subject to the above interval uncertainty can be formulated as the following binary integer program:

$$\min \quad \sum_{\{i,j\} \in E} c_{ij} \sum_{(s,t) \in S} (d'_{st} + \hat{d}_{st})(y_{ij}^{st} + y_{ji}^{st}) \tag{36}$$

$$\text{s.t.} \quad \sum_{j:\{i,j\} \in E} \left(y_{ij}^{st} - y_{ji}^{st}\right) = \begin{cases} 1 & i = s \\ -1 & i = t \\ 0 & \text{otherwise} \end{cases} \qquad \forall i \in V,\ \forall (s,t) \in S \tag{37}$$

$$y_{ij}^{st} \in \{0,1\} \qquad \forall \{i,j\} \in E,\ \forall (s,t) \in S. \tag{38}$$

As for the nominal problem (10)-(12) corresponding to the nominal traffic matrix $D' = (d'_{st})_{s,t \in Q}$, this robust version can be solved in polynomial time.

Since it may be overly pessimistic to assume that all demands simultaneously vary within the corresponding uncertainty intervals so as to adversely affect the solution, we consider a positive integer parameter Γ, $1 \leq \Gamma \leq |S|$, which allows to adjust the trade-off between the VPN robustness and its degree of conservatism as in the general approach for robust discrete optimization problems under data uncertainty proposed in [5, 6]. In order to avoid over-dimensioned VPNs, we minimize the maximum reservation cost while protecting us against the extreme behaviour

of at most Γ of the demands. More precisely, we consider the following robust VPN provisioning problem:

$$\min \quad \sum_{\{i,j\}\in E} c_{ij}x_{ij} \tag{39}$$

$$\text{s.t.} \quad \sum_{j:\{i,j\}\in E} \left(y_{ij}^{st} - y_{ji}^{st}\right) = \begin{cases} 1 & i = s \\ -1 & i = t \\ 0 & \text{otherwise} \end{cases} \qquad \forall i \in V,\ \forall (s,t) \in S \tag{40}$$

$$\sum_{(s,t)\in S} d'_{st}(y_{ij}^{st} + y_{ji}^{st}) \ +$$

$$\max_{\{\tilde{S} \mid \tilde{S}\subseteq S, |\tilde{S}|\leq\Gamma\}} \sum_{(s,t)\in\tilde{S}} \hat{d}_{st}\ (y_{ij}^{st} + y_{ji}^{st}) \leq x_{ij} \quad \forall \{i,j\} \in E \tag{41}$$

$$y_{ij}^{st} \in \{0,1\} \qquad \forall \{i,j\} \in E,\ \forall (s,t) \in S \tag{42}$$

$$x_{ij} \geq 0 \qquad \forall \{i,j\} \in E, \tag{43}$$

where $\tilde{S}$ denotes a subset of S of cardinality at most Γ. We refer to this robust variant of the problem as *Rob-G*. It is worth pointing out that the general probabilistic guarantees derived for the extreme behaviour of more than Γ parameters in [5] are also valid in our case.

As for *Sym-G* and *Asym-G*, this robust variant of the VPN provisioning problem admits a compact linear MIP formulation.

Proposition 2 *The robust VPN provisioning problem (39)-(43) has the following equivalent linear mixed-integer programming formulation:*

$$\min \quad \sum_{\{i,j\}\in E} c_{ij}x_{ij} \tag{44}$$

$$\text{s.t.} \quad \sum_{j:\{i,j\}\in E} \left(y_{ij}^{st} - y_{ji}^{st}\right) = \begin{cases} 1 & i = s \\ -1 & i = t \\ 0 & \text{otherwise} \end{cases} \qquad \forall i \in V,\ \forall (s,t) \in S \tag{45}$$

$$\sum_{(s,t)\in S} d'_{st}(y_{ij}^{st} + y_{ij}^{st}) + \Gamma\pi_{ij}^{0} + \sum_{(s,t)\in S} \pi_{ij}^{st} \leq x_{ij} \quad \forall \{i,j\} \in E \tag{46}$$

$$\pi_{ij}^{0} + \pi_{ij}^{st} \geq \hat{d}_{st}(y_{ij}^{st} + y_{ji}^{st}) \qquad \forall \{i,j\} \in E,\ \forall (s,t) \in S \tag{47}$$

$$y_{ij}^{st} \in \{0,1\} \qquad \forall \{i,j\} \in E,\ \forall (s,t) \in S \tag{48}$$

$$\pi_{ij}^{0},\ \pi_{ij}^{st},\ x_{ij} \geq 0 \qquad \forall \{i,j\} \in E,\ \forall (s,t) \in S. \tag{49}$$

Proof: As in [5, 6], we first consider the constraints whose parameters are subject to uncertainty, namely constraints (41). Given a vector $\bar{\mathbf{y}} \in \{0,1\}^{|E|\times|S|}$, for each $\{i,j\} \in E$ the problem

$$\max_{\{\tilde{S} \mid \tilde{S}\subseteq S, |\tilde{S}|\leq\Gamma\}} \sum_{(s,t)\in\tilde{S}} \hat{d}_{st}\ (\bar{y}_{ij}^{st} + \bar{y}_{ji}^{st}) \tag{50}$$

is equivalent to

$$\max \quad \sum_{(s,t)\in S} \alpha_{st}\ \hat{d}_{st}\ (\bar{y}_{ij}^{st} + \bar{y}_{ji}^{st}) \tag{51}$$

$$\text{s.t.} \quad \sum_{(s,t)\in S} \alpha_{st} \leq \Gamma \tag{52}$$

$$\alpha_{st} \in \{0,1\} \qquad \forall (s,t) \in S. \tag{53}$$

The key observation here is that the above problem viewed as a linear program by relaxing the integrality of α_{st} variables has always a binary optimal solution. Therefore, it can be replaced with

$$\max \quad \sum_{(s,t)\in S} \alpha_{st}\ \hat{d}_{st}\ (\bar{y}_{ij}^{st} + \bar{y}_{ji}^{st}) \tag{54}$$

$$\text{s.t.} \quad \sum_{(s,t)\in S} \alpha_{st} \leq \Gamma \tag{55}$$

$$0 \leq \alpha_{st} \leq 1 \qquad \forall (s,t) \in S, \tag{56}$$

which admits the following dual:

$$\min \quad \Gamma \pi^0_{ij} + \sum_{(s,t)\in S} \pi^{st}_{ij} \tag{57}$$

$$\text{s.t.} \quad \pi^0_{ij} + \pi^{st}_{ij} \geq \hat{d}_{st}(\bar{y}^{st}_{ij} + \bar{y}^{st}_{ji}) \quad \forall \{i,j\} \in E,\ \forall (s,t) \in S \tag{58}$$

$$\pi^0_{ij},\ \pi^{st}_{ij} \geq 0 \qquad \forall \{i.j\} \in E,\ \forall (s,t) \in S. \tag{59}$$

By strong duality this dual is feasible and bounded and has the same optimal objective function value as the primal problem (51)-(53). Substituting (57)-(59) in (39)-(43) yields (44)-(49). ∎

Unlike for the robust discrete optimization problems with $0-1$ variables considered in [5], there is unfortunately strong evidence that the robust VPN provisioning problem is substantially harder to solve than the associated nominal problem, that is (36)-(38) with $\hat{d}_{st} = 0$ for all $(s,t) \in S$, which can be solved in polynomial time.

Proposition 3 *The robust VPN provisioning problem (39)-(43) is* NP*-hard.*

Proof: We proceed by polynomial-time reduction from the following version of the Satisfiability problem.

> 3-SAT: Given a set of m clauses $C_1, \ldots, C_m$ in n Boolean variables $x_1, \ldots, x_n$ and their complements $\overline{x}_1, \ldots, \overline{x}_n$ with exactly 3 literals per clause, does there exist a truth assignment for the variables that satisfies all the clauses?

This problem is known to be NP-complete even when restricted to instances in which each Boolean variable x_j occurs (as x_j or $\overline{x}_j$) in at most 5 clauses [13]. The construction is similar to the one used to establish that it is NP-complete to decide whether in a given graph k distinct pairs of nodes can be connected with k edge-disjoint paths.

For any such instance of 3-SAT we construct a special instance of the robust VPN provisioning problem, defined by a graph $G = (V, E)$ with $c_{ij} = 1$ for all $\{i,j\} \in E$, a set of terminals $Q \subseteq V$, appropriate nominal demands and deviations between each pair of terminals and $\Gamma = 1$, such that the former instance of 3-SAT is satisfiable if and only if the second instance admits a robust VPN of total cost at most $5n + 4m$. For each variable x_j in the 3-SAT instance, we consider two terminals s_j and t_j in Q connected by two separate parallel paths corresponding to the variable x_j and its complement $\overline{x}_j$. Each one of these (s_j, t_j)-paths consists of exactly 5 edges and has 4 intermediate nodes. For each clause C_i, we consider two other terminals v_i and w_i in Q connected by three separate parallel paths that correspond to the three literals in the clause. Also these (v_i, w_i)-paths consist of 5 edges. The paths associated to the pairs of terminals (s_j, t_j), with $1 \leq j \leq n$, and (v_i, w_i), with $1 \leq i \leq m$, must intersect in the appropriate way. Suppose a clause C_{i_1} of 3-SAT contains the literals x_{j_1}, $\overline{x}_{j_2}$ and x_{j_3}, the three separate parallel paths corresponding to these literals are constructed as follows. The first (v_{i_1}, w_{i_1})-path shares exactly one edge (the third one) with the path connecting terminals s_{j_1} and t_{j_1} that corresponds to variable x_{j_1}; the second (v_i, w_i)-path shares exactly one edge (the third one) with the path connecting s_{j_2} and t_{j_2} that corresponds to $\overline{x}_{j_2}$; the third (v_i, w_i)-path shares exactly one edge (the third one) with the path connecting s_{j_3} and t_{j_3} that corresponds to x_{j_3}. Since each Boolean variable occurs in at most 5 clauses and each (s_j, t_j)-path consists of 5 edges, we can make sure that each edge of any (s_j, t_j)-path (corresponding to some x_j or $\overline{x}_j$) belongs to at most one (v_i, w_i)-path corresponding to a literal of a clause. Note that by construction all paths in G which connect any (s_j, t_j) (respectively (v_i, w_i)) terminal pair but are not (s_j, t_j)-paths (respectively (v_i, w_i)-paths) contain more than 5 edges.

With the above graph G and set of terminals $Q \subseteq V$, we consider the nominal demands $d'_{s_j t_j} = 0$ for all j and $d'_{v_i w_i} = 0$ for all i, and the deviations $\hat{d}_{s_j t_j} = 1$ for all j and $\hat{d}_{v_i w_i} = 1$ for all i. Note that the nominal demands and deviations for all other pairs of terminals in Q are set

to zero. Since $\Gamma = 1$ and each (v_i, w_i)-path shares exactly one edge with one of the (s_j, t_j)-paths, asking whether there exists a robust VPN with total reservation cost at most $5n + 4m$ amounts to deciding whether it is possible to route a unit of flow from s_j to t_j (i.e., to select one of the two alternative 5-edge (s_j, t_j)-paths) for every j, $1 \leq j \leq n$, and a unit of flow from v_i to w_i for every i, $1 \leq i \leq m$ (i.e., to select one of the three alternative 5-edge (v_i, w_i)-paths) so that for each i the selected (v_i, w_i)-path shares exactly one edge with a selected (s_j, t_j). Note that, due to unit costs, the total reservation cost cannot be smaller than $5n + 5m - m = 5n + 4m$. Indeed, a path with at least 5 edges is needed to connect each one of the n (respectively m) terminal pairs (s_j, t_j) (respectively (v_i, w_i)) and each selected (v_i, w_i)-path shares at most one edge with one of the selected (s_j, t_j)-paths.

Given any truth assignment for the 3-SAT instance, it is straightforward to select appropriate routing paths for the n pairs of terminals (s_j, t_j) and m pairs of terminals (v_i, w_i) based on the truth values of the variables and literals (at least one literal in each clause is true). Conversely, it is easy to derive from any such $n + m$ paths (where each selected (v_i, w_i)-path shares exactly one edge with one of the selected (s_j, t_j)-paths) a truth assignment for the original instance of 3-SAT.

Since demands are assumed to be routed along single paths, the reduction still holds for nonzero nominal demands d' for all (s_j, t_j) and (v_i, w_i) terminal pairs. ∎

Note that an important difference with respect to the $0-1$ robust discrete optimization problems considered in [5] lies in the the fact that here each uncertain parameter $\hat{d}_{st}$ multiplies several binary variables y_{ij}^{st}, see (36) and (41), instead of a single one.

In Section 5 we report computational results obtained by tackling this compact linear MIP formulation for medium-to-large-size instances with Cplex 8.1 MIP solver.

4 An exact solution method

Since practical VPNs can contain hundreds of terminals in networks with thousands of nodes, and our flow formulations of *Asym-G*, *Sym-G* and *Rob-G* are not viable for such size networks, we use more flexible path formulations, described in the next subsection, and adopt a column generation approach. As we are facing linear mixed-integer programs, the path formulations are tackled within a branch-and-price framework, discussed in Subsection 4.2. To evaluate the quality of the upper bounds found by the branch-and-price algorithm, we devise a cutting plane procedure which provides lower bounds. This procedure, described in Subsection 4.3, also help dealing with the well-known *tailing off* effect (i.e., the generation of spurious columns –paths– that do not improve the objective function value of the linear relaxation), which can substantially affect the performance of column generation. Cutting planes are not used throughout the branch-and-price algorithm, but only in the initial column generation phase performed in the root node: after each pricing iteration, we run one iteration of the cutting plane procedure.

4.1 Path formulations

Let us consider path variables instead of flow variables. As traffic is unsplittable, these variables are binary. Further notation is needed: P denotes the set of all possible oriented paths between any two given nodes in Q, P_{ij} the set of all paths in P containing the edge $\{i, j\} \in E$, and P^{st} the set of paths between the two demand nodes s and t.

For each path $p \in P$, we consider a binary variable z_p that is equal to 1 if and only if the path p, implicitly defined between two nodes s and t, is used to satisfy the demand d_{st}. The path formulation for *Asym-G* can then be expressed as follows:

$$\min \quad \sum_{\{i,j\} \in E} c_{ij} x_{ij} \tag{60}$$

$$\text{s.t.} \quad \sum_{p \in P^{st}} z_p \geq 1 \qquad \forall (s,t) \in S \tag{61}$$

$$\sum_{(s,t) \in S} d_{st} \sum_{p \in P^{st} \cap P_{ij}} z_p \leq x_{ij} \qquad \forall \{i,j\} \in E \tag{62}$$

$$\sum_{t\neq s} d_{st} \leq b_s^+,\ \sum_{t\neq s} d_{ts} \leq b_s^- \quad \forall s \in Q \tag{63}$$
$$d_{st} \geq 0 \quad \forall (s,t) \in S \tag{64}$$
$$z_p \in \{0,1\} \quad \forall p \in P \tag{65}$$
$$x_{ij} \geq 0 \quad \forall \{i,j\} \in E. \tag{66}$$

Constraints (61) ensure demand satisfaction by imposing that at least one path is used between each terminal pair, while constraints (62) define the capacity to be reserved on each edge $\{i,j\}$. As in Section 2.2, the worst-case capacity on edge $\{i,j\}$ can be determined by solving the linear program

$$x_{ij} \geq \max \sum_{(s,t)\in S} d_{st} \sum_{p\in P^{st}\cap P_{ij}} z_p \tag{67}$$
$$\sum_{t\neq s} d_{st} \leq b_s^+ \quad \forall s \in Q \tag{68}$$
$$\sum_{t\neq s} d_{ts} \leq b_s^- \quad \forall s \in Q \tag{69}$$
$$d_{st} \geq 0 \quad \forall (s,t) \in S \tag{70}$$

whose dual problem is:

$$x_{ij} \geq \min \sum_{s\in Q} (b_s^+ \omega_{ij}^{s+} + b_s^- \omega_{ij}^{s-}) \tag{71}$$
$$\omega_{ij}^{s+} + \omega_{ij}^{t-} \geq \sum_{p\in P^{st}\cap P_{ij}} z_p \quad \forall (s,t) \in S \tag{72}$$
$$\omega_{ij}^{s+},\ \omega_{ij}^{s-} \geq 0 \quad \forall s \in Q, \tag{73}$$

where the dual variables ω_{ij}^{s+} and ω_{ij}^{s-} correspond to constraints (68) and (69), respectively. Thus we obtain the linear mixed-integer path-based formulation for *Asym-G*:

$$\min \sum_{\{i,j\}\in E} c_{ij} x_{ij} \tag{74}$$
$$\text{s.t.} \sum_{p\in P^{st}} z_p \geq 1 \quad \forall\, (s,t) \in S \tag{75}$$
$$\sum_{s\in Q} (b_s^+ \omega_{ij}^{s+} + b_s^- \omega_{ij}^{s-}) \leq x_{ij} \quad \forall \{i,j\} \in E \tag{76}$$
$$\omega_{ij}^{s+} + \omega_{ij}^{t-} \geq \sum_{p\in P^{st}\cap P_{ij}} z_p \quad \forall\, (s,t) \in S,\ \forall\, \{i,j\} \in E \tag{77}$$
$$z_p \in \{0,1\} \quad \forall\, (s,t) \in S,\ \forall p \in P^{st} \tag{78}$$
$$\omega_{ij}^{s+},\ \omega_{ij}^{s-},\ x_{ij} \geq 0 \quad \forall\, \{i,j\} \in E,\ \forall s \in Q. \tag{79}$$

Since for*Sym-G* constraints (68)-(69) are replaced by

$$\sum_{t\neq s} d_{st} + \sum_{t\neq s} d_{ts} \leq b_s \quad \forall s \in Q,$$

we have the following formulation:

$$\min \sum_{\{i,j\}\in E} c_{ij} x_{ij}$$
$$\text{s.t.} \sum_{p\in P^{st}} z_p \geq 1 \quad \forall\, (s,t) \in S$$
$$\sum_{s\in Q} b_s\ \omega_{ij}^{s} \leq x_{ij} \quad \forall \{i,j\} \in E$$

$$\omega_{ij}^s + \omega_{ij}^t \geq \sum_{p \in P^{st} \cap P_{ij}} z_p \quad \forall\,(s,t) \in S,\ \forall\,\{i,j\} \in E$$
$$z_p \in \{0,1\} \qquad \forall\,(s,t) \in S,\ \forall p \in P^{st}$$
$$\omega_{ij}^s,\ x_{ij} \geq 0 \qquad \forall\,\{i,j\} \in E,\ \forall s \in Q,$$

where ω_{ij}^s is the dual variable corresponding to the edge $\{i,j\} \in E$ and terminal $s \in Q$.

A similar linear path-based formulation is obtained for *Rob-G* by replacing constraints (68)-(70) with

$$d_{st} = d'_{st} + \alpha_{st}\hat{d}_{st} \quad \forall (s,t) \in S \tag{80}$$
$$\sum_{(s,t)\in S} \alpha_{st} \leq \Gamma \tag{81}$$
$$0 \leq \alpha_{st} \leq 1 \quad \forall (s,t) \in S, \tag{82}$$

where α_{st} are the variables. Specifically we have:

$$\begin{aligned}
\min \quad & \sum_{\{i,j\}\in E} c_{ij}x_{ij} & \\
\text{s.t.} \quad & \sum_{p\in P^{st}} z_p \geq 1 & \forall\,(s,t) \in S \\
& \sum_{(s,t)\in S} d'_{s,t} \sum_{p\in P^{st}\cap P_{ij}} z_p + \Gamma\mu_{ij}^0 + \sum_{(s,t)\in S} \mu_{ij}^{st} \leq x_{ij} & \forall\{i,j\} \in E \\
& \mu_{ij}^{st} \geq \hat{d}_{st} \sum_{p\in P^{st}\cap P_{ij}} z_p - \mu_{ij}^0 & \forall\,\{i,j\} \in E,\ \forall\,(s,t) \in S \\
& z_p \in \{0,1\} & \forall\,(s,t) \in S,\ \forall p \in P^{st} \\
& \mu_{ij}^0,\ \mu_{ij}^{st},\ x_{ij} \geq 0 & \forall\{i,j\} \in E,\ \forall\,(s,t) \in S
\end{aligned}$$

with the dual variables μ_{ij}^0 corresponding to constraints (81) and μ_{ij}^{st} to the upper bounds in constraints (82).

4.2 A branch-and-price algorithm

To take advantage of these path formulations and solve large practical instances of *Asym-G*, *Sym-G* and *Rob-G*, we combine column generation and branch-and-bound. This joint approach, known as branch-and-price, has been introduced by Barnhart et al. [2] to solve large integer programs; an application to a multicommodity flow problem with integer flow variables can be found in [3].

For *Asym-G*, we start from a path formulation (74)-(79) with a small set P_0^{st} of paths for each terminal pair (s,t). At least one path per terminal pair is needed to ensure feasibility, but we take the K shortest paths from s to t with respect to the edge costs c_{ij}. After relaxing the integrality constraints, we obtain the *Restricted Linear Problem* (RLP) and solve it with primal simplex, retrieving the values of the dual variables $\bar{\sigma}_{st}$, $\bar{\xi}_{ij}$, $\bar{\eta}_{ij}^{st}$ of constraints (75), (76) and (77), respectively.

Consider a terminal pair (s,t). A variable z_p corresponding to a path $p \in P^{st}$ has reduced cost $-\bar{\sigma}_{st} + \sum_{\{i,j\}\in p} \bar{\eta}_{ij}^{st}$. All variables included in RLP have null or positive reduced cost after the primal simplex is called, but there may exist a z_p, not included in the current formulation, with a negative reduced cost. We seek one such variable for each terminal pair (s,t) by solving the so-called *pricing problem*.

We do not enumerate all paths in the set of remaining paths $P^{st} \setminus P_0^{st}$, as its cardinality may be exponential in the number of vertices. Instead, we solve a shortest path problem on a directed graph $G_\eta(s,t)$ whose arcs (i,j) correspond to edges in G, and have a cost $\bar{\eta}_{ij}^{st}$. If the length of such a shortest path p is smaller than $\bar{\sigma}_{st}$, then z_p has negative reduced cost and can be included in RLP.

The column generation procedure can be summarized as follows:

1. Build a formulation (74)-(79) with the set P_0^{st} of K shortest paths for every $(s,t) \in S$;
2. Obtain RLP by relaxing the integrality constraints;
3. Solve RLP, obtaining a primal solution $(\bar{x}_{ij}, \bar{\omega}_{ij}^{s+}, \bar{\omega}_{ij}^{s-}, \bar{z}_p)$ and the associated dual solution $(\bar{\sigma}_{st}, \bar{\xi}_{ij}, \bar{\eta}_{ij}^{st})$;
4. For each terminal pair $(s,t) \in S$:
   - Build an auxiliary undirected graph $G_{\bar{\eta}}(s,t)$ such that the length of each edge is $\bar{\eta}_{ij}^{st}$;
   - Find the shortest path $\tilde{p}$ in $G_{\bar{\eta}}(s,t)$ and let the length of $\tilde{p}$ be $l_{\bar{\eta}}^*(s,t)$;
   - If $l_{\bar{\eta}}^*(s,t) < \bar{\sigma}_{st}$, then add the related variable $z_{\tilde{p}}$ to RLP;
5. If at least one variable has been added, go to step 3. Otherwise, dual feasibility is obtained and RLP is solved.

The procedure is applied until no new path with negative reduced cost is found. Upon termination the current solution is an optimal solution of RLP. If one or more z_p variables are fractional, we divide the RLP by applying a branching step. The resulting subproblems are relaxed and solved with the technique described above, and so are all subproblems corresponding to nodes in the branch-and-bound tree.

It is worth pointing out that branching on one variable z_p may unbalance the branch-and-bound tree, or even make the algorithm loop: if a variable z_p is fixed to zero but the pricing procedure finds a path $p' \equiv p$ with negative reduced cost, a variable $z_{p'}$ is added even if path p is forbidden. Therefore the following branching rule is used in a branch-and-bound node N_k with at least one fractional $z_{\check{p}}$ variable related to a terminal pair (s,t). We choose an edge $\check{e}$ contained in $\check{p}$, then create two new nodes N_{k+1} and N_{k+2}, such that all path variables in N_{k+1} for terminal pair (s,t) associated to paths containing $\check{e}$ are set to zero, while in N_{k+2} their sum must be equal to one. Once the constraints

$$\sum_{p \in P^{st}: \check{e} \in p} z_p = 0 \qquad \text{and} \qquad \sum_{p \in P^{st}: \check{e} \in p} z_p = 1$$

are added to the subproblems associated to N_{k+1} and respectively N_{k+2}, the pricing problem is solved by a shortest path computation which takes into account the branching constraints at upper levels of the branch-and-bound tree.

The branch-and-price algorithm we have described for the *Asym-G* version of the problem can be easily adapted to *Sym-G* and *Rob-G* uncertainty.

4.3 A cutting plane procedure for providing lower bounds

Let us consider the flow formulation (13)-(18) of *Asym-G*. For any subset of edges $F \subseteq E$, we use the notation $x(F) = \sum_{\{i,j\} \in F} x_{ij}$ and, similarly, for any subset of arcs $F' \subset A$ the notation $y^{st}(F') = \sum_{(i,j) \in F'} y_{ij}^{st}$. For any subset of nodes $W \subset V$, the *cut* $\delta(W)$ is the set of edges with only one end-node in W, i.e., $\delta(W) = \{\{i,j\} \in E : i \in W, j \notin W\}$. For any subset $W \subset V$, the *directed cut* $\delta'(W)$ is the set of arcs with the tail in W and the head in $V \setminus W$.

Given any subset $W \subset V$, if there exists a non-empty set of terminal pairs $S' = \{(s,t) \in S : s \in W, t \in V \setminus W\}$, then for each one of these terminal pairs (s,t) at least one flow variable associated to an arc of the directed cut $\delta'(W)$ must be non-zero, that is,

$$y^{st}(\delta'(W)) \geq 1. \tag{83}$$

From (16) we obtain the following family of inequalities:

$$\sum_{(i,j) \in \delta'(W)} (\omega_{ij}^{s+} + \omega_{ij}^{t-}) \geq 1 \qquad \forall (s,t) \in S : |\{s,t\} \cap W| = 1 \tag{84}$$

that only involve ω variables and that are satisfied by any feasible solution of *Asym-G*.

Consider now the capacity $x(\delta(W))$ needed across a cut $\delta(W)$ so as to support the demands between all terminal pairs whose endpoints are on different shores, then we must have:

$$x(\delta(W)) \geq \sum_{(s,t)\in S:|\{s,t\}\cap W|=1} d_{st}. \tag{85}$$

Given the traffic uncertainty, the right-hand side of (85) is not known a priori and $x(\delta(W))$ has to be large enough in the worst case scenario. Since the maximum traffic across a cut $\delta(W))$, denoted by $d(\delta(W))$, amounts to

$$\max\left\{\sum_{(s,t)\in S:|\{s,t\}\cap W|=1} d_{st} : \sum_{t:t\neq s} d_{ts} \leq b_s^+ \ \ \forall s \in Q,\ \sum_{t:t\neq s} d_{st} \leq b_s^- \ \ \forall s \in Q,\ d_{st} \geq 0 \ \ \forall (s,t) \in S\right\},$$

any feasible solution of *Asym-G* must satisfy $x(\delta(W)) \geq d(\delta(W))$. As x_{ij} is defined in constraints (15), we can write equivalently:

$$\sum_{\{i,j\}\in\delta(W)} \sum_{s\in Q} (b_s^+ \omega_{ij}^{s+} + b_s^- \omega_{ij}^{t-}) \geq d(\delta(W)). \tag{86}$$

The *demand cut-set inequalities* (84) and the *capacity cut-set inequalities* (86) express two necessary conditions for supporting all valid traffic matrices.

Inequalities (84) and (86) are not violated by a solution of the linear relaxation of the formulation (13)-(18), as they are implied by the flow conservation constraints (14). However, a *cut formulation* including only the ω variables and a subset of these inequalities provides a lower bound to *Asym-G*. As for (86), we may get rid of the x variables and express the objective function in terms of the ω variables only:

$$\sum_{\{i,j\}\in E} c_{ij} \sum_{(s,t)\in S} (b_s^+ \omega_{ij}^{s+} + b_s^- \omega_{ij}^{t-}). \tag{87}$$

The goal is then to minimize (87) subject to inequalities (84) and (86). A cutting plane procedure for obtaining a lower bound on the optimal value of *Asym-G* takes a small initial set of such inequalities and repeatedly add violated cuts identified through efficient separation procedures. While separating inequalities (84) requires solving a maximum-flow problem, and hence is easy, separating inequalities (86) can be shown to be NP-hard.

We have decided to derive dual (lower) bounds by using inequalities (84). Consider $G = (V, E)$ and the set of values (b_s^+, b_s^-), $\forall s \in Q$. Let Δ denote a subset of all possible triplets $\{s, t, \delta(W)\}$, where $W \subset V$ and $|\{s,t\} \cap W| = 1$. A lower bound is given by the following linear program:

$$\begin{aligned} & \min && \sum_{\{i,j\}\in E} c_{ij} \sum_{(s,t)\in S} (b_s^+ \omega_{ij}^{s+} + b_s^- \omega_{ij}^{t-}) \\ (P_{\text{dual}}) \quad & \text{s.t.} && \sum_{(i,j)\in\delta'(W)} (\omega_{ij}^{s+} + \omega_{ij}^{t-}) \geq 1 \qquad \forall (s,t,W) \in \Delta. \end{aligned}$$

Since this problem has no z nor y variables, it is quickly solved for a reasonable number of inequalities.

The cutting plane procedure can be summarized as follows:

1. Let $\Delta := \emptyset$; $k := 0$;
2. Solve (P_{dual}), obtaining values $\tilde{\omega}_{ij}^{s+}$ and $\tilde{\omega}_{ij}^{s-}$ for all $\{i,j\} \in E$ and $s \in Q$;
3. *feasible* := TRUE;
4. For each $(s,t) \in S$:
   - Let $\tilde{G}_{st} = (V, A)$ be an auxiliary graph where $A = \{(i,j) : \{i,j\} \in E\}$ and let $c_{ij} = c_{ji} = \omega_{ij}^{s+} + \omega_{ij}^{t-}$ for all $(i,j) \in A$;

- Solve the maximum-flow/minimum-cut problem over $\tilde{G}_{st} = (V, A)$ with capacities c_{ij} and let $\delta(W)$ be a minimum capacity cut;
- If the capacity of $\delta(W)$ is smaller than 1, set $\Delta := \Delta \cup (s, t, W)$ and *feasible* := FALSE;

5. If *feasible* = TRUE, then stop and otherwise goto step 2.

Inequalities (84) and (86) are easily adapted to *Sym-G*. From (34) and (83) we obtain the two following families of valid inequalities:

$$\sum_{(i,j)\in\delta'(W)} (\omega_{ij}^s + \omega_{ij}^t) \geq 1 \quad \forall\ W \subset V,\ \forall (s,t) \in S : |\{s,t\} \cap W| = 1$$

$$\sum_{\{i,j\}\in\delta(W)} \sum_{s\in Q} b_s\ \omega_{ij}^s \geq d(\delta(W)) \quad \forall\ W \subset V.$$

Similar cuts can also be derived for *Rob-G*. Consider the relaxation of (50) equivalent to (54)-(56):

$$\begin{array}{lll} \max & \sum_{(s,t)\in S} d_{st}(\bar{y}_{ij}^{st} + \bar{y}_{ji}^{st}) & \\ \text{s.t.} & & \\ (\pi_{ij}^0) & \displaystyle\sum_{(s,t)\in S} \frac{d_{st} - d'_{st}}{\hat{d}_{st}} \leq \Gamma & \\ (\sigma_{ij}^{st}) & -d_{st} \leq -d'_{st} & \forall (s,t) \in S \\ (\rho_{ij}^{st}) & d_{st} \leq d'_{st} + \hat{d}_{st} & \forall (s,t) \in S, \end{array}$$

where π_{ij}^0, σ_{ij}^{st} and ρ_{ij}^{st} are the corresponding dual variables. It is easy to show that constraints (46) and (47) can be replaced by

$$\left(\Gamma + \sum_{(s,t)\in S} d'_{st}/\hat{d}_{st}\right)\pi_{ij} + \sum_{(s,t)\in S} \left((d'_{st} + \hat{d}_{st})\rho_{ij}^{st} - d'_{st}\sigma_{ij}^{st}\right) \leq x_{ij} \qquad \forall \{i,j\} \in E$$

$$\pi_{ij}^0/\hat{d}_{st} - \sigma_{ij}^{st} + \rho_{ij}^{st} \geq y_{ij}^{st} + y_{ji}^{st} \qquad \forall \{i,j\} \in E,\ \forall (s,t) \in S$$

$$\pi_{ij}^0,\ \sigma_{ij}^{st},\ \rho_{ij}^{st} \geq 0 \qquad \forall \{i,j\} \in E,\ \forall (s,t) \in S$$

and that the two types of valid inequalities for *Rob-G* are:

$$\sum_{(i,j)\in\delta'(W)} (\pi_{ij}^0/\hat{d}_{st} - \sigma_{ij}^{st} + \rho_{ij}^{st}) \geq 1 \qquad \forall\ W \subset V,\ \forall (s,t) \in S : |\{s,t\} \cap W| = 1$$

$$\sum_{\{i,j\}\in\delta(W)} \left(\left(\Gamma + \sum_{(s,t)\in S} d'_{st}/\hat{d}_{st}\right)\pi_{ij}^0 + \sum_{(s,t)\in S} \left((d'_{st} + \hat{d}_{st})\rho_{ij}^{st} - d'_{st}\sigma_{ij}^{st}\right)\right) \geq d(\delta(W)) \quad \forall\ W \subset V.$$

In order to find both lower and upper bounds, we consider a combined branch-and-price and cutting plane algorithm, referred to as BPC, where an iteration of the cutting plane procedure is run after each pricing iteration of the column generation. This provides a good estimate of the quality of the current solution. Stopping whenever the gap is small enough allows saving a number of pricing iterations that, in many column generation algorithms, tend to generate new columns (paths) with negative reduced cost even if they do not decrease the objective function value.

5 Computational results

We have tested the compact linear MIP formulations and our BPC algorithm for *Sym-G*, *Asym-G* and *Rob-G* on medium-to-large-size network topologies. The following instances have been considered:

bhv3/6/13: instances of a multicommodity flow problem studied in [3];

arpanet, eon, latadl, nsf, pacbell, toronto, usld: topologies of well-known backbone networks found in the IEEE literature;

res1/5/6/7/8/9, at-cep, ny-cep, nor-sun: instances of different multicommodity flow problems found at `http://www.di.unipi.it/di/groups/optimize/Data/MMCF.html#Rsrv`

stein1/2/3/4: a set of Steiner tree problem instances with 50 and 75 nodes, available from `http://www.brunel.ac.uk/depts/ma/research/jeb/orlib/steininfo.html`;

n45, n49, n147: general multicommodity flow instances;

g200: a network topology with 200 nodes and 914 links [4];

t3-X, t4-X: a set of backbone networks with 250 and 304 nodes randomly generated with the `gt-itm` software (`http://www.cc.gatech.edu/projects/gtitm/gt-itm/`).

All instances are available from `ftp://ftp.elet.polimi.it/users/Pietro.Belotti/mcf/vpn` in a pseudo-DIMACS format and in AMPL data format.

Since single VPNs are considered, the set Q of terminals has been randomly selected as a small subset of V with a density $|Q|/|V|$ of approximately 15%. The values of b_s, b_s^+, b_s^-, d'_{st}, and $\hat{d}_{st}$ have been generated based on realistic random traffic matrices.

All tests have been carried out with a Pentium Xeon 2.8 GHz processor, running under Linux with 2 GB of memory available. The BPC algorithm has been implemented in C++ using the open-source COIN/Bcp software framework [9] and Cplex 8.1 as LP solver, while Cplex 8.1 MIP solver has been used for our compact formulations. Initially we generate, for each terminal pair (s,t), K shortest paths from s to t through the HREA algorithm described in [14].

The computational results are summarized in five tables that include the following information:

- the instance name and the network parameters (the cardinality of V, E and of the set of terminals $Q \subseteq V$),
- the time (t_{root}) spent by column generation in the root node, i.e, the time required to solve the relaxed problem, starting with $K = 5$ paths for each terminal pair,
- the time (t_{tot}) spent in total by the BPC algorithm,
- the time (t_{cf}) spent by Cplex 8.1 MIP solver on the linear flow-based compact formulation,
- #paths and #cuts: the number of paths and cuts generated by the pricing and the cutting plane iterations.

All times are expressed in seconds.

A time limit of two hours has been given both for the BPC algorithm and for tackling the compact flow-based formulations with Cplex 8.1 MIP solver. If the time limit is reached before obtaining an optimal solution, we report in brackets the gap between the best feasible solution and the best lower bound that have been found. A "–" indicates that no feasible solution was found (in the t_{tot} column it means that the branch-and-bound part was not performed). The label "*mem*" indicates that the problem could not be solved because of excessive memory requirements, namely more than 2GB of RAM. In the BPC algorithm, if the time limit is reached while solving the linear relaxation, the gap is given in brackets in the t_{root} column.

According to Table 1, the small-size *Sym-G* instances (with up to 40 nodes) are solved very rapidly and the performance of Cplex 8.1 on the compact linear MIP formulation and of the BPC algorithm are comparable.

The computational results obtained for larger *Sym-G* instances are reported in Table 2. Our compact flow-based formulation turns out to be very tight so as to yield the optimal solution within less than a minute even for the large problem "n147". For larger instances, however, it pays to develop a specialized combined branch-and-price and cutting plane method because the compact linear MIP formulation leads to excessive memory requirements. Our BPC algorithm, which performs better on "n147" and on a few smaller instances such as "n45" and "stein2", allows to solve "g200" and "t3-3" optimally within the two hour time limit and to tackle larger instances. Unlike in all other experiments, for "t3-0" we have set $K = 20$ (instead of $K = 5$) and let the BPC method run for 252286.68 sec. The gap is in fact reduced to 3.24% after 79293.58 sec. and then progressively to 0.94%. Tuning the value of K and allowing for more than two hours of computing time, we can also obtain gaps below a few percentage points for the other large instances. Note that, for all instances which have been solved to optimality, an optimal solution is already found at the root node of the branch-and-price tree. The BPC algorithm stops after the initial column generation phase because the solution found has the same value of the optimal integer solution. In very few cases branch-and-bound steps are performed (and the branch-and-price time taken after the RLP is solved, $t_{\text{tot}} - t_{\text{root}}$, is negligible in most cases) and they do not improve the lower bound. Since the number of paths that are generated during the column generation phase is moderate with respect to the number of terminal pairs, the approach is viable even for larger instances. The insertion of cutting planes has a dramatic effect in limiting the tailing off of the objective function value when additional paths are added. The cuts, which are of the same order of magnitude as the number of paths, help close the gap within a very short computing time.

Another interesting result emerged from preliminary experiments performed on small, randomly generated *Sym-G* instances. We have observed that for most instances even the linear relaxation has an integer solution, i.e., all flow variables y are either 0 or 1; in the few cases where at least one y variable is fractional, restoring the integrality constraints gives an integer solution with the same cost. Moreover, for most *Sym-G* instances the edges $\{i, j\}$ with positive capacity x_{ij} formed a tree; in the remaining cases, imposing a tree structure on the solution, i.e., solving the related *Sym-T* problem, yielded a solution with the same cost. Thus our experimental results support the following conjecture:

Sym-G always admits an optimal tree solution.

The same conjecture was also made by Erlebach and Rüegg [10] and it has been communicated to us that Hurkens, Keijsper and Stougie have a proof of the conjecture for networks consisting of a single cycle [8]. Since these authors were not aware of the formulations introduced in Section 2, it remains to be seen whether our present work will help settle this conjecture for more general classes of graphs. Note that the situation for *Asym-G* differs slightly: most instances have an integer optimum with the same cost as the linear relaxation optimal solution, but we have found some instances with a integer optimum with larger cost.

Computational results for *Asym-G* are reported in Table 3. The compact flow-based formulation is remarkably tight and effective also in this case. All mid-size instances can be solved to optimality in a few minutes with Cplex 8.1 MIP solver, except for "stein4" for which no integer solution could be found before the time limit. Among the large networks, only "t3-4" could be solved to optimality, whereas the remaining "tX-X" and "g200" could not be solved due to excessive memory requirements. In general, asymmetric instances appear to be more challenging than symmetric ones for the BPC approach. Since for 9 out of the 40 instances under consideration the gap remains large beyond the time limit, we do not report BPC computing times. It has still to be determined whether the substantial difference observed for several instances is mainly due to the remarkable quality of the compact linear MIP formulation or to a relevant margin for improving the BPC algorithm, by including for instance efficient memory management procedures that purge unused paths/cuts and ω variables.

The results obtained for *Rob-G* are summarized in Tables 4 and 5. Here Γ is taken equal to 15% of the total number of terminal pairs, but other intermediate values yield similar results. Although the robust VPN provisioning problem leads to less conservative VPNs by exploiting the available traffic statistics, Tables 4 and 5 indicate that the corresponding compact linear MIP formulation is much harder to tackle with Cplex 8.1 than those for *Asym-G* and *Sym-G*. However, the BPC algorithm is remarkably effective in solving *Rob-G* instances and it compares

Table 1: Results for small *Sym-G* instances: BPC algorithm and the compact linear MIP formulation solved with Cplex.

very favorably with Cplex 8.1 even for small-size instances. As for *Sym-G*, the compact flow-based formulation for *Rob-G* requires more memory than the BPC algorithm in which paths and cuts are dynamically generated starting from small initial sets. For all instances larger than "n147", the compact formulations do not fit in a RAM of 2 GB whereas the path and cut formulations, which have a potentially exponential size, lead to optimal solutions in less than 2 hours. Note that only a limited number of paths and cuts are generated.

6 Concluding remarks

We have addressed the network design problem under traffic uncertainty arising when provisioning Virtual Private Networks. Sufficient capacity must be reserved on the links of a large underlying public network so as to support all valid traffic matrices between a given set of terminals while minimizing total reservation costs.

The first contribution of this paper consists in new compact linear MIP formulations which allow to solve to optimality medium-to-large-size instances of *Asym-G* and *Sym-G* within less than 15 minutes of computing time. These flow-based formulations also provide significant experimental support to the conjecture about *Sym-G* and *Sym-T*.

To exploit traffic statistics that are available for provisioned VPNs, we have proposed a robust VPN provisioning problem, *Rob-G*, which leads to less conservative reservations. The compact linear MIP formulation for this NP-hard problem is more challenging to tackle with a commercial solver than the one for *Asym-G*.

The combined branch-and-price and cutting plane algorithm we have developed, based on path and cut formulations, performs well on large *Sym-G* instances and remarkably well on all *Rob-G* instances. Further work is needed to establish whether it can also compare favourably with the compact formulations for large *Asym-G* instances. To this purpose, we are currently studying an evolution of our BPC approach that limits the memory requirements due to the generation of paths/cuts and to unused ω variables and that integrates cut generation within the branch-and-bound framework.

The linear mixed-integer programming formulations and algorithm presented in this paper can be extended to the general multicommodity network design problem under polyhedral demand uncertainty, where the demand matrix is assumed to lie in a polyhedron or a union of polyhedra [1].
