

Dynamic sampling algorithms for multi-stage stochastic programs with risk aversion*

A.B. Philpott[†] and V.L. de Matos[‡]

February 9, 2011

Abstract

We consider the incorporation of a time-consistent coherent risk measure into a multi-stage stochastic programming model, so that the model can be solved using a SDDP-type algorithm. We describe the implementation of this algorithm, and study the solutions it gives for an application of hydro-thermal scheduling in the New Zealand electricity system. The performance of policies using this risk measure at different levels of risk aversion is compared with the risk-neutral policy.

1 Introduction

Multi-stage stochastic linear programming models have been solved using decomposition for over thirty years, originating with the seminal work of [2], but there are still very few implementations of these models in commercial settings. The classical version of this model constructs a scenario tree that branches at each stage. Even with a small number of outcomes per stage, the size of the scenario tree grows exponentially with the number of stages. In two-stage problems with many scenarios, the sample average approximation approach enables large-scale problems to be solved to within reasonable error bounds [10]. However, as argued by [21], the exponential growth of the scenario tree makes all but the smallest instances of multi-stage problems intractable for sample average approximation.

One area in which multi-stage stochastic linear programming models are widely applied is in the long-term scheduling of water resources, in particular in hydro-thermal electricity systems. This problem involves determining a policy of releasing water from reservoirs for hydro-electricity generation and generating from thermal plant over some planning horizon of

months or years so as to meet the future demand for electricity at lowest expected fuel cost. The first models (dating back to [13],[11]) for these problems used dynamic programming, a tool that was confined to systems with one or two reservoirs, unless reservoir aggregation heuristics (see e.g. [23]) are used.

An effort to model systems with multiple reservoirs led to the development in the 1980s and 1990s of various multi-stage stochastic linear programming models (see e.g. [9]) using scenario trees. Stochastic Dual Dynamic Programming (SDDP) [15] was developed as a response to the problem of dealing with a rapidly growing scenario tree. This method approximates the future cost function of dynamic programming using a piecewise linear outer approximation, defined by cutting planes or *cuts* computed by solving linear programs. This avoids the curse of dimensionality that arises from discretizing the state variables. The intractability arising from a branching scenario tree is avoided by essentially assuming stagewise independent uncertainty. This allows cuts to be shared between different states, effectively collapsing the scenario tree.

The ability to share cuts under some specific forms of stagewise dependency as discussed by Infanger and Morton [8] is now included in most commercial implementations of the SDDP algorithm. Monte Carlo sampling is also used in estimating bounds. These features make SDDP look more like an approximate dynamic programming method than a multi-stage stochastic linear programming algorithm. Commercial implementations of SDDP are in widespread use around the world, and are used to schedule hydro-electric plant in a number of South American countries including Brazil and Chile.

The standard implementations of SDDP are risk neutral, in that they seek policies that minimize expected cost. In hydro-thermal systems this cost comes about from thermal fuel and penalty costs, such as shortages. A cost-minimizing system operator would accept occasional shortages in electricity if this made the long-run cost of fuel a minimum. In practice, shortages do not occur very often, but when they do, they are so disruptive that politicians and system operators would wish to avoid them. It therefore makes sense to compute hydro-thermal scheduling policies that are risk averse. In some circumstances it is possible to have a significantly less risky policy with a modest increase in expected cost.

In this paper we describe a version of SDDP that models risk. Our work is based on the recent paper by Shapiro [22], but draws also on work by [19] and [20]. Our measure of risk in each stage is a convex combination of expectation and conditional value at risk [17], [18]. This makes it coherent as defined by [1]. The risk measure we use also satisfies a dynamic programming recursion, and so it is time-consistent in the sense defined by [19]. The recursive nature of its definition, and its convexity also admits approximation using cutting planes, and so we can modify SDDP to accommodate this.

Several other authors have developed SDDP implementations that account for risk. In [7], Iliadis *et al* describe a hydro-thermal scheduling model that accounts for the conditional value at risk of accumulated revenue shortfall at the end of the planning horizon, however there are few details in this paper about its implementation in the SDDP method. Guigues and Sagastizabal [5] study a rolling horizon model that repeatedly solves and implements the solution to a single stage problem with chance constraints. Guigues and Romisch [4]

present a general framework for extended polyhedral risk measures in the context of SDDP. The general risk measure they use makes use of a state space augmented by a vector of costs representing a possible history up to the current time. In contrast the model proposed by Shapiro [22] uses one extra state variable in each stage and so is more straightforward to compute. As we shall see, even in this case the algorithm takes some time to converge to a good solution.

Our aim in this paper is to demonstrate that risk-averse policies for this class of large-scale stochastic programming problems can be computed reasonably easily using SDDP-type methods. Moreover, by simulating these policies on a representation of a real hydro-thermal system, we are able to draw some conclusions about the value of these models as decision tools.

The paper is laid out as follows. In the next section, for completeness, we describe the risk-neutral SDDP algorithm, and describe a version of this model using a Markov chain to represent stagewise dependence in our model. This section can be skipped by readers who are familiar with this class of algorithms. In section 3, we define conditional value at risk and describe how this is implemented in a multi-stage context in section 4. We describe this in some detail, starting with a two-stage model to build the reader's intuition. The final model that we discuss in this section uses a Markov chain with states that can be used to adapt the level of risk aversion to depend on expectations of future events. In section 5 and 6 we describe a model of the New Zealand electricity system and some computational results of experiments where this approach is applied to this system, respectively. Section 7 concludes the paper.

2 Multi-stage stochastic linear programming

In this section we review the Stochastic Dual Dynamic Programming (SDDP) algorithm proposed by [15] as a solution strategy for risk neutral multi-stage stochastic linear programming. As mentioned in the Introduction, instead of solving all possible scenarios of the multi-stage scenario tree, SDDP attacks a small sample of the scenarios to build a policy that is defined by a piecewise linear outer approximation of the future cost for each stage. This function is constructed using cutting planes called Benders cuts, or just *cuts*. In the SDDP algorithm the scenario tree is decoupled by node, in which the first stage problem is assumed to be deterministic and can be denoted by

$$\begin{aligned} z = \min \quad & c_1^\top x_1 + \mathbb{E}[Q_2(x_1, \omega_2)] \\ \text{s.t.} \quad & A_1 x_1 = b_1, \\ & x_1 \geq 0. \end{aligned} \tag{1}$$

where $x_1 \in \mathbb{R}^n$ is the first stage decision and $c_1 \in \mathbb{R}^n$ a cost vector, A_1 is a $m \times n$ matrix, and $b_1 \in \mathbb{R}^m$. We denote by $Q_2(x_1, \omega_2)$ the second stage costs associated with decision x_1 and realization $\omega_2 \in \Omega_2$. Since the scenario tree is finite, the support Ω_t for all stages $t = 2, 3, \dots, T$ is also finite. The problem to be solved in each stage t , state x_{t-1} , and realization ω_t can be written as

$$\begin{aligned}
Q_t(x_{t-1}, \omega_t) = \min \quad & c_t^\top x_t + \mathbb{E}[Q_{t+1}(x_t, \omega_{t+1})] \\
\text{s.t.} \quad & A_t x_t = b_t(\omega_t) - E_t x_{t-1}, \quad [\pi_t(\omega_t)] \\
& x_t \geq 0,
\end{aligned} \tag{2}$$

where $x_t \in \mathbb{R}^n$ is the decision in stage t and c_t its cost, A_t and E_t denote $m \times n$ matrices. The random vector $b_t(\omega_t) \in \mathbb{R}^m$ depends on the realization ω_t . In the last stage we assume either that $\mathbb{E}[Q_{T+1}(x_T, \omega_{T+1})] = 0$, or that there is a convex function that defines the expected future cost after stage T .

In the SDDP algorithm $\mathbb{E}[Q_{t+1}(x_t, \omega_{t+1})]$ is replaced by θ_{t+1} which is defined by a set of cuts given by

$$\theta_{t+1} + \bar{\pi}_{t+1,k}^\top E_{t+1} x_t \geq \bar{g}_{t+1,k} \quad \text{for } k = 1, 2, \dots, K. \tag{3}$$

where K is the number of cuts. Here $\bar{\pi}_{t+1,k} = \mathbb{E}[\pi_{t+1}(\omega_{t+1})]$, which defines the gradient $-\bar{\pi}_{t+1,k}^\top E_{t+1}$ and the intercept $\bar{g}_{t+1,k}$ for cut k in stage t , where

$$\bar{g}_{t+1,k} = \mathbb{E}[Q_{t+1}(x_t^k, \omega_{t+1})] + \bar{\pi}_{t+1,k}^\top E_{t+1} x_t^k.$$

The SDDP algorithm performs a sequence of major iterations known as the *forward pass* and the *backward pass* to build an approximately optimal policy, defined by cuts. In each forward pass, a set of N scenarios is sampled from the scenario tree and decisions are taken for each node of those N scenarios, starting in the first stage and moving forward up to the last stage. In this step the final volumes in the reservoirs and the costs of each node in all scenarios are saved.

At the end of the forward pass, a convergence criterion is tested, and if it is satisfied then the algorithm is stopped, otherwise it starts the backward pass, which is defined below. In the standard version of SDDP, convergence is achieved when the estimate of a lower bound on expected cost at the first stage (called the *Lower Bound*), which is the sum of the present cost ($c_1^\top x_1$) and estimated future cost (operation policy), is statistically close to an estimate of the expected total operation cost obtained by evaluating the policy defined by the cuts over several scenarios (called the *Upper Bound*). The total operation cost for each scenario is the sum of the present cost ($c_t^\top x_t$) in all stages.

If the convergence test fails, SDDP improves the policy using a backward pass that adds a cut to each stage problem, starting at the last stage and working backwards to the first. In each stage t we solve the next stage problems for all possible realizations (Ω_{t+1}). The values of the objective functions and dual variables at optimality are averaged over all realizations to define a cut that is added to all problems at stage t . In summary, the SDDP algorithm performs the following three steps repeatedly until a convergence criterion is satisfied.

1. Forward Pass

For $t = 1$ solve (1) and save x_1 and z ;

For $t = 2, \dots, T$ and $s = 1, \dots, N$,

Solve (2), where ω_t is defined by s , and save $x_t(s)$ and $Q_t(x_{t-1}, \omega_t)$.

2. Convergence Test

Calculate the Upper Bound: $z_u = c_1^\top x_1 + \frac{1}{S} \sum_{s=1}^S \sum_{t=2}^T c_t^\top x_t(s)$

$$\sigma_u = \sqrt{\frac{(c_1^\top x_1 + \sum_{t=2}^T c_t^\top x_t(s))^2 - z_u^2}{S}};$$

Calculate the Lower Bound: $z_l = z$;

Assuming a 90% confidence interval and $S \geq 30$, stop if

$$z_u - \frac{1.96}{\sqrt{S}} \sigma_u < z_l < z_u + \frac{1.96}{\sqrt{S}} \sigma_u,$$

otherwise go to the Backward Pass.

3. Backward Pass

For $t = T, \dots, 2$, and $s = 1, \dots, N$,

For $\omega_t \in \Omega_t$, solve (2) using $x_{t-1}(s)$ and save $\pi_t(\omega_t)$ and $Q_t(x_{t-1}, \omega_t)$;

Calculate a cut (3) and add it to all nodes in stage $t - 1$.

In our implementation of the algorithm above we choose $N = 1$. This has been shown by [3] to give better results than the standard choice ($N = 200$). In our experiments we also choose to run the SDDP algorithm for a fixed number of iterations, rather than using the above stopping criterion. This test, which was proposed by [15], can be misleading (see e.g. [6],[22]).

2.1 Markov process in the SDDP algorithm

The algorithm described above assumes that the random variables are stage-wise independent. In many settings this is not a suitable model, and there is some correlation over time. A popular approach to dealing with this is to model the random variables as an autoregressive process with independent errors (see e.g. [12]). In this paper we describe a different approach in which the random variables have a probability distribution that depends on an underlying state which follows a Markov process. This state becomes another state dimension of the dynamic program. When the state is continuous (as in an autoregressive process) we require that the future cost function is convex as a function of this state. When the state is discrete (as in a finite Markov chain), we must enumerate a future cost function for each value that the state may take. For each state variable there is a set of possible realizations at each stage. During the course of the algorithm, when cuts are added, we record a set of cuts for each state in the Markov chain instead of just one for the stage. A similar approach has been described by [14] in the context of modelling uncertainty in the objective function (e.g. from electricity prices) as well as in the constraint right-hand sides.

This construction is best illustrated with an example. Suppose that the Markov chain has two states, 1 and 2, which are shown in Figure 1 with the transition probabilities q ,

Figure 1: Example of state transitions.

Figure 2: Markov process states.

$1 - q$, and p , $1 - p$. Here and henceforth we will colour nodes in state 1 black and nodes in state 2 white.

We augment the state space with a new state variable which takes values 1 and 2. Suppose that the random realizations in each stage can take only four values, ξ_a , ξ_b , ξ_c , ξ_d , and that these can be classified into two states as shown in Figure 2.

For a three-stage problem, this corresponds to a scenario tree as shown in Figure 3, in which the black nodes correspond to state 1 and the white nodes represent state 2. From Figure 3 it is possible to see that the set of descendent nodes is the same for any given stage, but they may have different probabilities depending on the value of the current state. Therefore, cuts cannot be shared directly. However as the dual solutions in one node are valid for all nodes with the same realization in that stage, one can use the solutions to compute a cut for each state by using the appropriated probabilities.

There are two possible approaches to deal with this situation. In the first one we calculate in each iteration a partial cut for each state and both are used in all states, which means that in the case of Figure 3 the third stage problems would generate the following pair of cuts for the second stage:

$$\begin{aligned} \theta_{3ab} + \frac{\pi_{3a} + \pi_{3b}}{2} E_3 x_2 &\geq \frac{Q(\xi_{3a}) + Q(\xi_{3b})}{2} + \frac{\pi_{3a} + \pi_{3b}}{2} E_3 x_2^* \\ \theta_{3cd} + \frac{\pi_{3c} + \pi_{3d}}{2} E_3 x_2 &\geq \frac{Q(\xi_{3c}) + Q(\xi_{3d})}{2} + \frac{\pi_{3c} + \pi_{3d}}{2} E_3 x_2^* \end{aligned}$$

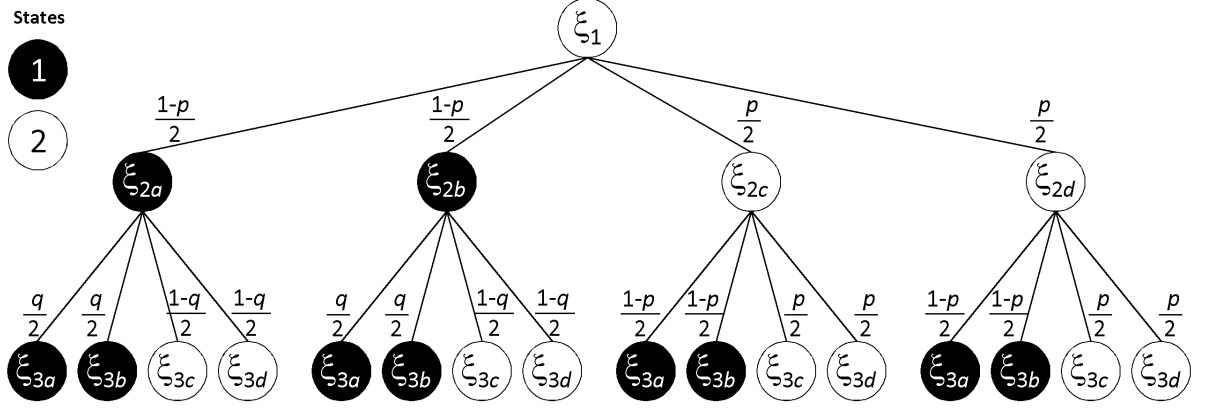

Figure 3: Scenario tree with the Markov Process.

In this *multi-cut* approach the future cost at stage 2 is represented by

$$\theta_{31} = q\theta_{3ab} + (1 - q)\theta_{3cd}$$

when the node corresponds to state 1 (black) and by

$$\theta_{32} = (1 - p)\theta_{3ab} + (p)\theta_{3cd}$$

when the node corresponds to state 2 (white).

Alternatively, the *single-cut* approach constructs the conditional expectation of each cut with the appropriate transition probabilities and stores a single extra cut in each state at stage 2. This gives

$$\begin{aligned} \theta_{31} + \left[q \frac{\pi_{3a} + \pi_{3b}}{2} + (1 - q) \frac{\pi_{3c} + \pi_{3d}}{2} \right] E_3 x_2 &\geq \left[q \frac{Q(\xi_{3a}) + Q(\xi_{3b})}{2} + (1 - q) \frac{Q(\xi_{3c}) + Q(\xi_{3d})}{2} \right] \\ &+ \left[q \frac{\pi_{3a} + \pi_{3b}}{2} + (1 - q) \frac{\pi_{3c} + \pi_{3d}}{2} \right] E_3 x_2^* \quad \text{for state 1} \\ \theta_{32} + \left[(1 - p) \frac{\pi_{3a} + \pi_{3b}}{2} + p \frac{\pi_{3c} + \pi_{3d}}{2} \right] E_3 x_2 &\geq \left[(1 - p) \frac{Q(\xi_{3a}) + Q(\xi_{3b})}{2} + p \frac{Q(\xi_{3c}) + Q(\xi_{3d})}{2} \right] \\ &+ \left[(1 - p) \frac{\pi_{3a} + \pi_{3b}}{2} + p \frac{\pi_{3c} + \pi_{3d}}{2} \right] E_3 x_2^* \quad \text{for state 2} \end{aligned}$$

In both cases it is necessary to maintain two sets of cuts at each stage. In the first case, each node's problem will use both set of cuts, so the stage optimization problems will be larger, whilst in the second case each node will use only one set of cuts. Although, the size of each stage problem grows more quickly in the first case, the multi-cut strategy is expected to require fewer iterations to achieve convergence.

3 Risk measures

In this section we begin our discussion of how to make the policies generated by SDDP risk averse in the sense that they penalize large losses, without compromising the expected cost

too much. One common approach to measure the risk of a loss distribution of a given random variable Z is the $1 - \alpha$ *value at risk*, $\text{VaR}_{1-\alpha}[Z]$, that is defined by [18] as

$$\text{VaR}_{1-\alpha}[Z] = \inf_u \{u : \Pr(Z \leq u)\} \geq 1 - \alpha,$$

where α is typically chosen to be some small probability e.g. 0.05. This means that $\text{VaR}_{1-\alpha}[Z]$ is the left-side $(1 - \alpha)$ th percentile of the loss distribution. It is well known that even when Z is a convex function of a decision x , the function $\text{VaR}_{1-\alpha}[Z]$ is not guaranteed to be convex in x , which makes optimization difficult in general, and impossible in SDDP. The tightest convex safe approximation of $\text{VaR}_{1-\alpha}[Z]$ is called the *conditional value at risk*. This can be written [18] as

$$\text{CVaR}_{1-\alpha}[Z] = \inf_u \{u + \alpha^{-1} \mathbb{E}[Z - u]_+\},$$

where we write $[a]_+$ for $\max\{a, 0\}$.

In this paper we study a combination of the expected total cost and the conditional value at risk, as suggested by Shapiro [22]. Therefore, we use a risk measure

$$\rho(Z) = \beta \mathbb{E}[Z] + \gamma \text{CVaR}_{1-\alpha}[Z], \quad (4)$$

where β and γ are nonnegative. In practice it makes sense to choose $\beta > 0$ since $\text{CVaR}_{1-\alpha}[Z]$ on its own will disregard the effect of decisions on expected outcomes, which might result in expensive policies on average that we would wish to avoid if cheaper ones were possible with the same level of CVaR .

Conditional value at risk is an example of a coherent risk measure. According to [1] a function $\rho : \mathbb{R}^n \rightarrow \mathbb{R}$ is a *coherent risk measure* if ρ satisfies the following axioms for Z_1 and $Z_2 \in \mathbb{R}^n$.

- **Convexity:** $\rho(\alpha Z_1 + (1 - \alpha)Z_2) \leq \alpha \rho(Z_1) + (1 - \alpha)\rho(Z_2)$, for $\alpha \in [0, 1]$;
- **Monotonicity:** If $Z_1 \leq Z_2$, then $\rho(Z_1) \leq \rho(Z_2)$;
- **Positive homogeneity:** If $U \in \mathbb{R}$ and $U > 0$, then $\rho(UZ_1) = U\rho(Z_1)$;
- **Translation equivariance:** If $U \in \mathbb{R}$, then $\rho(\mathbb{I}U + Z_1) = U + \rho(Z_1)$.

The risk measure defined in (4) satisfies the first three axioms, and in order to satisfy the fourth (translation equivariance), we have

$$\begin{aligned} U + \rho(Z_1) &= \rho(\mathbb{I}U + Z_1) \\ &= \beta \mathbb{E}[\mathbb{I}U + Z_1] + \gamma \text{CVaR}_{1-\alpha}[\mathbb{I}U + Z_1] \\ &= \beta U + \beta \mathbb{E}[Z_1] + \gamma U + \gamma \text{CVaR}_{1-\alpha}[Z_1] \\ &= (\beta + \gamma)U + \beta \mathbb{E}[Z_1] + \gamma \text{CVaR}_{1-\alpha}[Z_1] \\ &= (\beta + \gamma)U + \rho(Z_1). \end{aligned}$$

so $\beta + \gamma = 1$. Therefore, we replace β and γ by $(1 - \lambda)$ and λ , respectively to give

$$\rho(Z) = (1 - \lambda) \mathbb{E}[Z] + \lambda \text{CVaR}_{1-\alpha}[Z] \quad (5)$$

yielding

$$\rho(Z) = (1 - \lambda)\mathbb{E}[Z] + \lambda \inf_u \{u + \alpha^{-1}\mathbb{E}[Z - u]_+\}.$$

The risk measure $\rho(Z)$ is equivalent to the *mean deviation from quantile* proposed by Miller and Ruszczyński [20], bearing in mind that in our setting we are minimizing Z . In this setting, the mean deviation from quantile measure is

$$\rho_d(Z) = \mathbb{E}[Z] + \lambda \min_{\eta} \sum_{i=1}^N p_i \max\left(\frac{1 - \alpha}{\alpha}(z_i - \eta), \eta - z_i\right) \quad (6)$$

in which N is the number of realizations of the discrete random variable Z . We have

$$\max\left(\frac{1 - \alpha}{\alpha}(z_i - \eta), \eta - z_i\right) = (\eta - z_i) + \max\left(\frac{1 - \alpha}{\alpha}(z_i - \eta) - (\eta - z_i), 0\right)$$

and

$$\frac{1 - \alpha}{\alpha}(z_i - \eta) - (\eta - z_i) = \frac{1}{\alpha} [(z_i - \eta) - \alpha(z_i - \eta) + \alpha(z_i - \eta)] = \frac{1}{\alpha}(z_i - \eta).$$

So,

$$\max\left(\frac{1 - \alpha}{\alpha}(z_i - \eta), \eta - z_i\right) = (\eta - z_i) + \max\left(\frac{1}{\alpha}(z_i - \eta), 0\right) \quad (7)$$

Therefore, by replacing (7) in (6) we obtain

$$\begin{aligned} \rho_d(Z) &= \mathbb{E}[Z] + \lambda \min_{\eta} \sum_{i=1}^N p_i \left[(\eta - z_i) + \max\left(\frac{1}{\alpha}(z_i - \eta), 0\right) \right] \\ &= \mathbb{E}[Z] - \lambda \mathbb{E}[Z] + \lambda \min_{\eta} (\eta + \sum_{i=1}^N p_i \max\left(\frac{1}{\alpha}(z_i - \eta), 0\right)) \\ &= \rho(Z) \end{aligned}$$

The measure ρ as defined is a single period measure, which is extended in [22] to a *dynamic risk measure* $\rho_{t,T}$ over $t = 1, 2, \dots, T$ following the general theory of [19]. To help the reader interpret the computational results it is worthwhile presenting a brief summary of this general construction. Given a probability space (Ω, \mathcal{F}, P) , a dynamic risk measure applies to a situation in which we have a random sequence of costs (Z_1, Z_2, \dots, Z_T) which is adapted to some filtration $\{0, \Omega\} = \mathcal{F}_1 \subset \mathcal{F}_2 \dots \subset \mathcal{F}_T \subset \mathcal{F}$ of σ -fields, where Z_1 is assumed to be deterministic. A dynamic risk measure is then defined to be a sequence of *conditional risk measures* $\{\rho_{t,T}\}$, $t = 1, 2, \dots, T$. Given a dynamic risk measure, we can derive a corresponding single-period risk measure using

$$\rho_t(Z_{t+1}) = \rho_{t,T}(0, Z_{t+1}, 0, \dots, 0).$$

By [19, Theorem 1], any time-consistent dynamic risk measure can then be constructed in terms of single-period risk measures ρ_t by the formula

$$\rho_{t,T}(Z_t, Z_{t+1}, \dots, Z_T) = Z_t + \rho_t(Z_{t+1} + \rho_{t+1}(Z_{t+2} + \dots + \rho_{T-2}(Z_{T-1} + \rho_{T-1}(Z_T)) \dots)).$$

In the next section we describe this construction in the special case in which we choose the single-period risk measure

$$\rho_t(Z) = (1 - \lambda_t)\mathbb{E}[Z \mid \mathcal{F}_t] + \lambda_t \inf_u \{u + \alpha^{-1}\mathbb{E}[Z - u \mid \mathcal{F}_t]_+\}.$$

4 Implementing a CVaR risk measure in SDDP

In this section we present the modelling strategy to optimize the coherent risk measure discussed in Section 3. This can be considered to be one of the main contributions of this paper, because although our approach is similar to the ones shown in [22] and [20], there are some important differences related to our solution strategy. In this section we omit a description of the basic SDDP algorithm, because the algorithm is exactly the same as the one presented in Section 2 except for the problems to be solved and the cut calculations.

To help understand how the stage problems are affected by our risk measure, we first consider a two-stage linear problem that aims to minimize the first stage cost plus the risk measure applied to the second stage costs. Here the first stage is deterministic and the second stage random variable has finite support Ω_2 . In this paper the stochastic process is going to be modelled by random variables only in the constraint right-hand side. This problem can be written as follows:

$$\begin{aligned} \text{SP: } \min \quad & c_1^\top x_1 + (1 - \lambda)\mathbb{E}[c_2^\top x_2] + \lambda u_2 + \lambda \alpha^{-1}\mathbb{E}[c_2^\top x_2 - u_2]_+ \\ \text{s.t.} \quad & A_1 x_1 = b_1, \\ & A_2 x_2(\omega) + E_2 x_1 = b_2(\omega), \quad \text{for all } \omega \in \Omega_2, \\ & x_1 \geq 0, \quad x_2(\omega) \geq 0, \quad \text{for all } \omega \in \Omega_2. \end{aligned}$$

We then replace $[c_2^\top x_2 - u_2]_+$ by $v_2(\omega)$ where

$$\begin{aligned} v_2(\omega) &\geq c_2^\top x_2(\omega) - u_2, & \text{for all } \omega \in \Omega_2, \\ v_2(\omega) &\geq 0, & \text{for all } \omega \in \Omega_2. \end{aligned}$$

As a consequence, the new 2-stage problem can be written as the following linear program:

$$\begin{aligned} \text{SP: } \min \quad & c_1^\top x_1 + (1 - \lambda)\mathbb{E}[c_2^\top x_2] + \lambda u_2 + \lambda \alpha^{-1}\mathbb{E}[v_2] \\ \text{s.t.} \quad & A_1 x_1 = b_1, \\ & A_2 x_2(\omega) + E_2 x_1 = b_2(\omega), \quad \text{for all } \omega \in \Omega_2, \\ & v_2(\omega) \geq c_2^\top x_2(\omega) - u_2, \quad \text{for all } \omega \in \Omega_2, \\ & x_1 \geq 0, \quad x_2(\omega) \geq 0, \quad v_2(\omega) \geq 0, \quad \text{for all } \omega \in \Omega_2. \end{aligned}$$

Observe in SP that there are two first-stage decisions to be made, x_1 , and the level u_2 that attains $\inf_u \{u + \alpha^{-1} \mathbb{E}[c_2^\top x_2 - u]_+\}$. Given choices of x_1 and u_2 the second-stage problem becomes:

$$\begin{aligned} \text{SP}(x_1, u_2): \quad & \min \quad (1 - \lambda) \mathbb{E}[c_2^\top x_2] + \lambda \alpha^{-1} \mathbb{E}[v_2] \\ & \text{s.t.} \quad A_2 x_2(\omega) = b_2(\omega) - E_2 x_1, & \text{for all } \omega \in \Omega_2, \\ & \quad v_2(\omega) - c_2^\top x_2(\omega) \geq -u_2, & \text{for all } \omega \in \Omega_2, \\ & \quad x_2(\omega) \geq 0, \quad v_2(\omega) \geq 0, & \text{for all } \omega \in \Omega_2. \end{aligned}$$

This decouples by nodes to give:

$$\begin{aligned} Q(x_1, u_2, \omega) = \min \quad & (1 - \lambda) c_2^\top x_2 + \lambda \alpha^{-1} v_2 \\ & \text{s.t.} \quad A_2 x_2 = b_2 - E_2 x_1, & [\pi_2(\omega)] \\ & \quad v_2 - c_2^\top x_2 \geq -u_2, & [\phi_2(\omega)] \\ & \quad x_2 \geq 0, \quad v_2 \geq 0. \end{aligned}$$

The optimal dual multipliers are shown in brackets on the right. By strong duality the optimal solution satisfies

$$Q(x_1, u_2, \omega) = \pi_2(\omega)^\top (b_2 - E_2 x_1) - \phi_2(\omega) u_2.$$

so SP can now be represented by

$$\begin{aligned} \text{SP:} \quad & \min \quad c_1^\top x_1 + \lambda u_2 + \mathbb{E}[Q(x_1, u_2, \omega)] \\ & \text{s.t.} \quad A_1 x_1 = b_1, \\ & \quad x_1 \geq 0. \end{aligned}$$

Benders decomposition can be used to compute the solution to SP, which we now represent by

$$\begin{aligned} \text{MP:} \quad & \min \quad c_1^\top x_1 + \lambda u_2 + \theta_2 \\ & \text{s.t.} \quad A_1 x_1 = b_1, \\ & \quad \theta_{2k} + \bar{\pi}_{2k}^\top E_2 x_1 + \bar{\phi}_{2k} u_2 \geq g_{2k}, \quad k = 1, 2, \dots, K \\ & \quad x_1 \geq 0. \end{aligned}$$

where k counts the cuts that are added to the Benders master problem and

$$\begin{aligned} \bar{\pi}_{2k} &= \mathbb{E}[\pi_{2k}], \\ \bar{\phi}_{2k} &= \mathbb{E}[\phi_{2k}], \\ g_{2k} &= \mathbb{E}[Q_2(x_{1k}^*, u_{2k}^*)] + \bar{\pi}_{2k}^\top E_2 x_{1k}^* + \bar{\phi}_{2k} u_{2k}^*. \end{aligned}$$

We can generalize this method to a T -stage problem, which we illustrate using notation for a three stage problem. In this case, SP can be written as follows:

$$\begin{aligned} \text{SP:} \quad & \min \quad c_1^\top x_1 + (1 - \lambda_2) \mathbb{E}[c_2^\top x_2 + (1 - \lambda_3) \mathbb{E}[c_3^\top x_3] + \lambda_3 u_3 + \lambda_3 \alpha_3^{-1} \mathbb{E}[c_3^\top x_3 - u_3]_+] + \lambda_2 u_2 \\ & \quad + \lambda_2 \alpha_2^{-1} \mathbb{E}[c_2^\top x_2 + \lambda_3 u_3 + (1 - \lambda_3) \mathbb{E}[c_3^\top x_3] + \lambda_3 u_3 + \lambda_3 \alpha_3^{-1} \mathbb{E}[c_3^\top x_3 - u_3]_+ - u_2]_+ \\ & \text{s.t.} \quad A_1 x_1 = b_1, \\ & \quad A_2 x_2(\omega_2) + E_2 x_1 = b_2(\omega_2), \quad \text{for all } \omega_2 \in \Omega_2, \\ & \quad A_3 x_3(\omega_3) + E_3 x_2(a(\omega_3)) = b_3(\omega_3), \quad \text{for all } \omega_3 \in \Omega_3, \\ & \quad x_1 \geq 0, \quad x_2(\omega_2) \geq 0, \quad x_3(\omega_3) \geq 0, \quad \text{for all } \omega_2 \in \Omega_2 \text{ and } \omega_3 \in \Omega_3. \end{aligned} \tag{8}$$

where, $a(\omega_t)$ denotes the ancestor of node ω_t . The last stage (third) can be decoupled from problem above and by nodes to give:

$$Q_3(x_2, u_3, \omega_3) = \min \quad (1 - \lambda_3)c_3^\top x_3 + \lambda_3\alpha_3^{-1}v_3$$

$$\text{s.t.} \quad \begin{aligned} A_3x_3 &= b_3 - E_3x_2, & [\pi_3(\omega_3)] \\ v_3 - c_3^\top x_3 &\geq -u_3, & [\phi_3(\omega_3)] \\ x_3 &\geq 0, \quad v_3 \geq 0. \end{aligned}$$

Assuming that $Q_3(x_2, u_3) = \mathbb{E}[Q_3(x_2, u_3, \omega_3)]$ and replacing it in (8) we can write SP as follows:

$$\text{SP: } \min \quad \begin{aligned} &c_1^\top x_1 + (1 - \lambda_2)\mathbb{E}[c_2^\top x_2 + \lambda_3u_3 + Q_3(x_2, u_3)] + \lambda_2u_2 \\ &+ \lambda_2\alpha^{-1}\mathbb{E}[c_2^\top x_2 + \lambda_3u_3 + Q_3(x_2, u_3) - u_2]_+ \end{aligned}$$

$$\text{s.t.} \quad \begin{aligned} A_1x_1 &= b_1, \\ A_2x_2(\omega_2) + E_2x_1 &= b_2(\omega_2), \quad \text{for all } \omega_2 \in \Omega_2, \\ x_1 &\geq 0, \quad x_2(\omega_2) \geq 0, \quad \text{for all } \omega_2 \in \Omega_2. \end{aligned}$$

We then replace $[c_2^\top x_2 + \lambda_3u_3 + Q_3(x_2, u_3) - u_2]_+$ by $v_2(\omega_2)$ where

$$\begin{aligned} v_2(\omega_2) &\geq c_2^\top x_2 + \lambda_3u_3 + Q_3(x_2, u_3) - u_2 \quad \text{for all } \omega_2 \in \Omega_2, \\ v_2(\omega_2) &\geq 0 \quad \text{for all } \omega_2 \in \Omega_2. \end{aligned}$$

As a consequence, the new 2-stage problem can be written:

$$\text{SP: } \min \quad c_1^\top x_1 + (1 - \lambda_2)\mathbb{E}[c_2^\top x_2 + \lambda_3u_3 + Q_3(x_2, u_3)] + \lambda_2u_2 + \lambda_2\alpha^{-1}\mathbb{E}[v_2]$$

$$\text{s.t.} \quad \begin{aligned} A_1x_1 &= b_1, \\ A_2x_2(\omega_2) + E_2x_1 &= b_2(\omega_2), \quad \text{for all } \omega_2 \in \Omega_2, \\ v_2(\omega_2) &\geq c_2^\top x_2 + \lambda_3u_3 + Q_3(x_2, u_3) - u_2, \quad \text{for all } \omega_2 \in \Omega_2, \\ x_1 &\geq 0, \quad x_2(\omega_2) \geq 0, \quad v_2(\omega_2) \geq 0, \quad \text{for all } \omega_2 \in \Omega_2. \end{aligned}$$

Given choices of x_1 and u_2 the problem SP becomes:

$$\text{SP}(x_1, u_2): \min \quad (1 - \lambda_2)\mathbb{E}[c_2^\top x_2 + \lambda_3u_3 + Q_3(x_2, u_3)] + \lambda_2\alpha^{-1}\mathbb{E}[v_2]$$

$$\text{s.t.} \quad \begin{aligned} A_2x_2(\omega_2) &= b_2(\omega_2) - E_2x_1, \quad \text{for all } \omega_2 \in \Omega_2, \\ v_2(\omega_2) - c_2^\top x_2 - \lambda_3u_3(\omega_2) - Q_3(x_2, u_3) &\geq -u_2, \quad \text{for all } \omega_2 \in \Omega_2, \\ x_2(\omega_2) &\geq 0, \quad v_2(\omega_2) \geq 0, \quad \text{for all } \omega_2 \in \Omega_2. \end{aligned}$$

This decouples by node to give:

$$Q_2(x_1, u_2, \omega_2) = \min \quad (1 - \lambda_2)(c_2^\top x_2 + \lambda_3u_3 + Q_3(x_2, u_3)) + \lambda_2\alpha^{-1}v_2$$

$$\text{s.t.} \quad \begin{aligned} A_2x_2 &= b_2(\omega) - E_2x_1, & [\pi_2(\omega_2)] \\ v_2 - c_2^\top x_2 - \lambda_3u_3 - Q_3(x_2, u_3) &\geq -u_2, & [\phi_2(\omega_2)] \\ x_2 &\geq 0, \quad v_2 \geq 0. \end{aligned}$$

Now if $Q_3(x_2, u_3)$ can be represented by K_3 cuts we obtain

$$\begin{aligned}
Q_2(x_1, u_2, \omega_2) = \min & \quad (1 - \lambda_2)(c_2^\top x_2 + \lambda_3 u_3 + \theta_3) + \lambda_2 \alpha^{-1} v_2 \\
\text{s.t.} & \quad A_2 x_2 = b_2 - E_2 x_1, & [\pi_2(\omega_2)] \\
& \quad v_2 - c_2^\top x_2 - \lambda_3 u_3 - \theta_3 \geq -u_2, & [\phi_2(\omega_2)] \\
& \quad \theta_3 + \bar{\pi}_{3k}^\top E_3 x_2 + \bar{\phi}_{3k} u_3 \geq g_{3k}, & k = 1, 2, \dots, K_3, \\
& \quad x_2 \geq 0, \quad v_2 \geq 0.
\end{aligned}$$

In general the t th stage of SP can be represented by

$$\begin{aligned}
Q_t(x_{t-1}, u_t, \omega_t) = \min & \quad (1 - \lambda_t)(c_t^\top x_t + \lambda_{t+1} u_{t+1} + \theta_{t+1}) + \lambda_t \alpha^{-1} v_t \\
\text{s.t.} & \quad A_t x_t = b_t(\omega) - E_t x_{t-1}, & [\pi_t(\omega_t)] \\
& \quad v_t - (c_t^\top x_t + \lambda_{t+1} u_{t+1} + \theta_{t+1}) \geq -u_t, & [\phi_t(\omega_t)] \\
& \quad \theta_{t+1} + \bar{\pi}_{t+1,k}^\top E_{t+1} x_t + \bar{\phi}_{t+1,k} u_{t+1} \geq g_{t+1,k}, & k = 1, 2, \dots, K_{t+1}, \\
& \quad x_t \geq 0, \quad v_t \geq 0.
\end{aligned} \tag{9}$$

where k counts the cuts that are added to the t th-stage Benders master problem and

$$\begin{aligned}
\bar{\pi}_{t+1,k} &= \mathbb{E}[\pi_{t+1,k}], \\
\bar{\phi}_{t+1,k} &= \mathbb{E}[\phi_{t+1,k}], \\
g_{t+1,k} &= \mathbb{E}[Q_{t+1}(x_{tk}^*, u_{t+1,k}^*)] + \bar{\pi}_{t+1,k} E_{t+1} x_{tk}^* + \bar{\phi}_{t+1,k} u_{t+1,k}^*.
\end{aligned}$$

Since each stage model is a linear program with uncertainty appearing on the right-hand side, we can apply the standard form of SDDP to solve the risk-averse model. Moreover the algorithm satisfies all the conditions in [16], and so it converges almost surely to the optimal policy, under mild conditions on the sampling process (e.g. independence).

One practical difficulty is obtaining reliable estimates of the upper bound on the cost of an optimal policy. The multi-stage setting with CVaR requires a conditional sampling process to estimate the cost of any policy, which would be prohibitively expensive for problems with many stages.

The absence of a good upper-bound estimate makes it difficult to check the convergence of the method. One possible approach is to stop the algorithm if the lower bound has not changed significantly for some iterations, but this does not guarantee that the current policy is close to optimal, even if one is interested only in the first stage action. Our approach is to run the algorithm until the risk-neutral version of the code has converged, and then use the same number of iterations for the risk-averse model.

4.1 Risk aversion with Markov Chain uncertainty

In Section 2.1 we discussed how to integrate a Markov chain model into the SDDP algorithm to solve a risk-neutral problem in which the uncertain data have some stagewise dependence. In our risk-averse model, the Markov chain can be implemented in exactly the same way, whereby we calculate one set of cuts for each Markov state, in each of which the u variable acts as an additional state variable like the reservoir levels.

Using Markov states to represent stagewise dependence in the uncertain parameters provides an opportunity to make the risk measure depend on the state of the Markov chain as discussed in [19]. In our setting, a simple dependence would retain the convex combination of expectation and conditional value at risk, and would choose λ_t to depend on the observed state in stage t . Unfortunately choosing λ_t to be dependent on the state in stage t is not possible in our model, because as one can see from (9) λ_t appears in the formulation of the problem to be solved in stage $t - 1$, when we are uncertain about the realization of the state in stage t .

In some circumstances we can approximate this form of state dependence by making λ_t depend on the observed state in the *previous* stage $t - 1$. For example, if the state in stage $t - 1$ leads to high costs in the future then we might choose λ_t close to 1 when this state is realized, and λ_t close to 0 when the opposite state is realized. This method relies on a Markov chain that has a certain amount of state persistence, so a realization of the expensive state in stage $t - 1$ is likely to persist into stage t . In the case of the previous example, a persistent model would have $p > 0.5$ and $q > 0.5$. If, on the other hand, the process is stagewise independent, then this choice of λ_t would not make sense as there would be no reason to change our risk attitude at stage t , based on the realization of the state at the previous stage.

As discussed in Section 2.1, when λ_t does not depend on the observed state in stage $t - 1$, the set of possible realizations and the formulation are the same for all states. Therefore, the stage t solutions in the backward pass are used to generate one cut for each state in stage $t - 1$ by using the appropriate transition probabilities. On the other hand, when λ_t depends on the observed state in stage $t - 1$, the formulation of problem (9) will depend on the observed state in stage $t - 1$ because of λ_t . This dependence means that we can compute cuts only for the states that are visited in the sampled scenarios, which means that the cut calculated in a specific scenario can only be added to the observed state. As a consequence, by assuming that λ_t depends on the observed state in stage $t - 1$ incurs some additional computational cost when compared to the independent λ_t .

As an illustration of the model with λ dependence, consider the example presented in Section 2.1, and let us assume that one would like to be less risk averse when the previous stage was in state 1. For example, we might choose $\lambda_t = 0.25$, when the realization at stage $t - 1$ belongs to State 1 and $\lambda_t = 0.75$, when the realization at stage $t - 1$ belongs to State 2. Figure 4 shows the scenario tree with the Markov Chain and the λ value for each stage and state, assuming that we start in a state 2 realization.

5 Application: Long-Term Hydrothermal Scheduling

In this section we describe the application of the risk-averse SDDP algorithm to a hydroelectric scheduling model developed for the New Zealand electricity system. The model consists of 33 hydro plants (5400 MW) and 12 thermal plants (2800 MW). We use a simplified transmission network \mathcal{N} comprising three buses: one for the South Island (South), one for the lower North Island (Hay) and one for the upper North Island (North) as shown in Figure

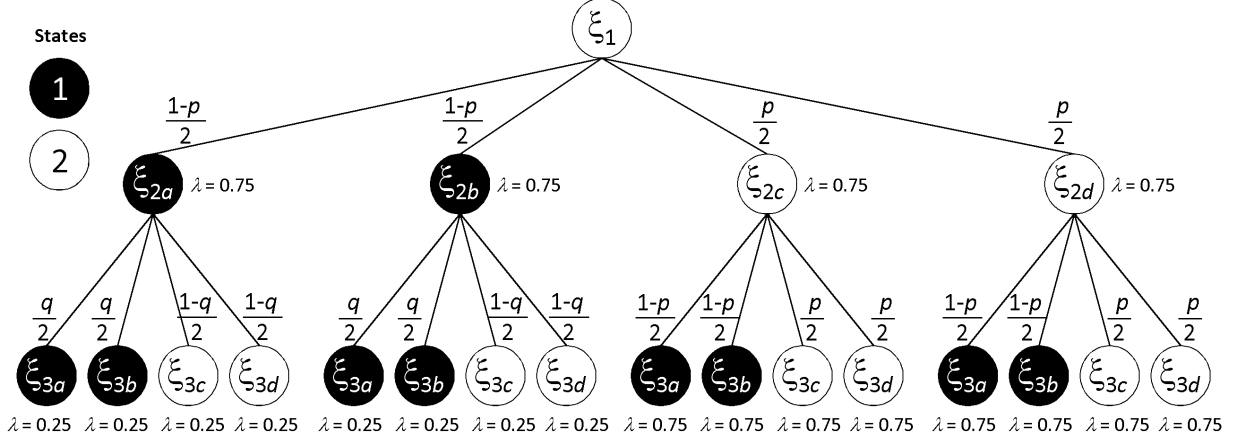

Figure 4: Risk-averse Markov process tree with risk aversion dependent on state in previous stage.

5. We model storage in eight hydro reservoirs in the South Island, and a single reservoir at the head of the Waikato chain of eight stations in the North Island. All other hydro stations are assumed to be run-of-river. All thermal plants are located in the upper North Island.

The formulation we solve is a stochastic dynamic programming problem in which at each stage $t = 1, 2, \dots, T$, the Bellman equation is approximated by a linear program. We first describe the general model (10) and then describe how the data specializes to the particular instance we solve¹. The description shown in this section is for the risk-neutral problem.

The objective of the model is to minimize the cost to meet the demand D_{it} in stage t at each bus $i \in \mathcal{N}$ plus the future cost θ_{t+1} that is approximated by cuts

$$\theta_{t+1} + \bar{\pi}_{t=1}^k v_{t+1} \geq g_{t+1}^k$$

as discussed in Section 2. We discriminate between thermal generation f_{pt} , at thermal plant $p \in \mathcal{T}(i)$ (that has capacity a_p and incurs a fuel cost η_p), and hydro generation $\gamma_m h_{mt}$, at hydro station $m \in \mathcal{H}(i)$ (that has capacity b_m , and is essentially free). We also assume that load shedding is modelled as thermal generation with higher marginal costs than the most

¹Details of the New Zealand hydro-thermal system used in this model can be found at <http://www.epoc.org.nz>.

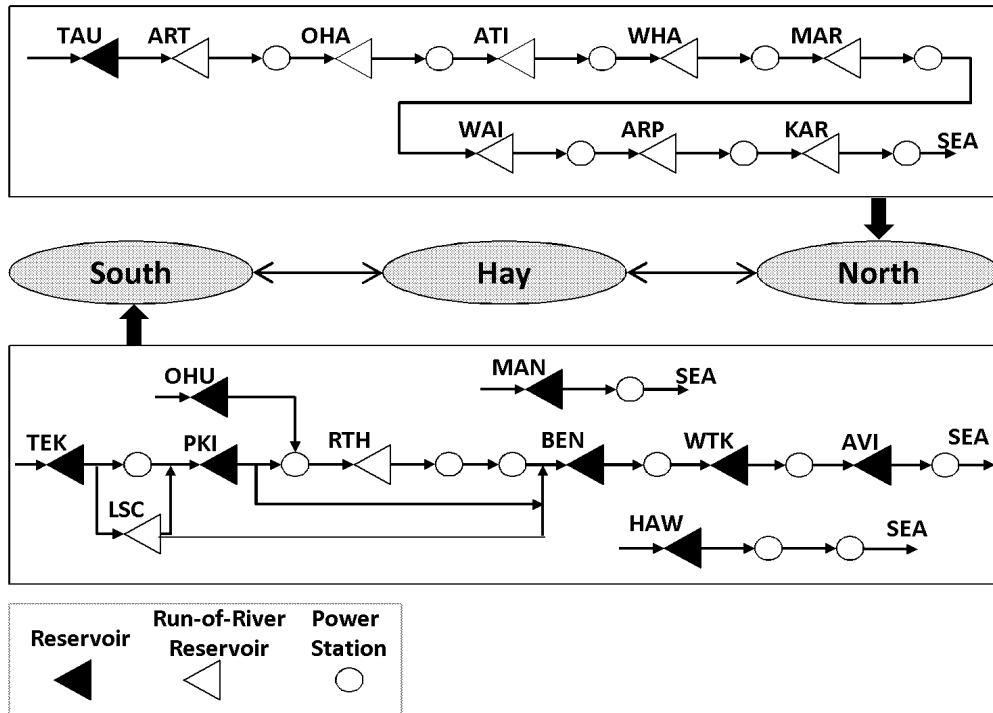

Figure 5: Representation of the New Zealand hydro-thermal scheduling model.

expensive thermal unit. This gives the following formulation at stage t :

$$\begin{aligned}
z_t(\omega) &= \min \sum_{i \in \mathcal{N}} \sum_{p \in \mathcal{T}(i)} \eta_p f_{pt} + \theta_{t+1} \\
\text{s.t.} \\
w_i(y_t) + \sum_{p \in \mathcal{T}(i)} f_{pt} + \sum_{m \in \mathcal{H}(i)} \gamma_m h_{mt} &= D_{it}, i \in \mathcal{N}, \\
v_{t+1} &= v_t - A(q_t + s_t) + \xi_t, \\
0 \leq f_{pt} \leq a_p, \quad p \in \mathcal{T}(i), i \in \mathcal{N}, \\
0 \leq q_{mt} \leq b_m, \quad 0 \leq s_{mt} \leq c_m, \quad m \in \mathcal{H}(i), \\
0 \leq v_{mt} \leq r_m, \quad m \in \mathcal{H}(i), i \in \mathcal{N}, \quad y \in Y, \\
\theta_{t+1} + \bar{\pi}_{t=1}^k v_{t+1} &\geq g_{t+1}^k, k \in \mathcal{C}(t+1).
\end{aligned} \tag{10}$$

The components of the vector y measure the flow of power in each transmission line. We denote the flow in the directed line from i to k by y_{ik} , where by convention we assume $i < k$. A negative value of y_{ik} denotes flow in the direction from k to i . In general we require that this vector lies in some convex set Y , which may model DC-load flow constraints arising from Kirchhoff's laws and thermal flow limits. The concave function $w_i(y)$ defines the amount of power arriving at node i for a given choice of y thus allowing one to model line losses.

The water balance constraints are represented by

$$v_{t+1} = v_t - A(q_t + s_t) + \xi_t$$

where v_t is the reservoir storage at the start of period t , s_t denotes spill in period t , and ξ_t is the uncontrolled inflow into the reservoir in period t . Storage, release and spill variables are subject to capacity constraints. The parameter γ_m , which varies by generating station m , converts the flow of water q_{mt} into electric power. The node-arc incidence matrix A represents all river-valley networks, and aggregates controlled flows that leave from each reservoir by spilling or generating or enter a reservoir by spilling or generating electricity upstream. In other words row i of $A(q_t + s_t)$ gives the total controlled flow out of the reservoir (or river junction) represented by row i , this being the sum of any release and spill of reservoir i minus the release and spill of any immediately upstream reservoir.

In the New Zealand model with three buses there are no loops, so Y represents line capacities only. We also assume that there are no line losses which gives

$$w_i(y) = \sum_{k < i} y_{ki} - \sum_{k > i} y_{ik}.$$

The time horizon of our model is one year with weekly time steps, so $T = 52$. We are using data from the calendar year 2006 and assume that in each stage the set of possible inflows is given by the historical inflows from 1987 to 2006, inclusive. As a consequence,

Markov State	North Island	South Island
WW	Wet	Wet
DW	Dry	Wet
WD	Wet	Dry
DD	Dry	Dry

Table 1: Markov states for the New Zealand LTHS problem.

in our problem we have a scenario tree that has 20 random realizations per stage (called *openings*) and 52 stages given a total of more than 2.25×10^{66} scenarios.

The inflows were modelled by estimating transitions between four states of a Markov chain as follows. First, historical inflows were aggregated into two groups corresponding to the South Island and North Island. We classified two possible states (wet and dry²) for each island, to give a total of four states as shown in Table 1. After grouping the outcomes into four sets corresponding to each state, the transition probabilities are estimated from the historical inflow sequence from 1987 to 2006, inclusive.

An inflow sequence is simulated by constructing a random sequence of 52 states, and then randomly sampling a weekly inflow record from the group of historical outcomes representing the simulated state in each week. To test the performance of candidate policies on a common benchmark, we assume throughout this paper that the Markov chain we construct in this way represents the true stochastic process of inflows. (It is certainly interesting to test how different approximations of the real inflow process affect the policies being computed, but we see this as a different modelling exercise to be explored in a separate study.)

As mentioned above, we assume that nine reservoirs (with a total capacity of 7.5 billion cubic metres) can store water from week to week, and the remaining reservoirs are treated as run-of-river plant with limited intra-week flexibility. In some cases we also have minimum or maximum flow constraints that are imposed by environmental resource consents. When this is the case total discharge limits are added to the model, and deviations of flows outside these limits are penalized in the objective function. Weekly demand is aggregated from historical records, and represented by a load duration curve with three blocks representing peak, off-peak, and shoulder periods.

6 Computational Experiments

In this section we present the results of computational experiments to evaluate the performance of the models discussed throughout this paper. In all experiments where λ_t is independent of the state at stage $t - 1$, we choose λ_t to be a fixed constant L for all stages t . Additionally, we assume $\lambda = 0$ for all cases in stage 1 and $T + 1$. We denote by “4 Ls”

²A historical outcome is considered to be a dry state if the sum of all inflows in the island is smaller than the historical average of the sum of all inflows. Otherwise, it is considered to be wet.

Case	λ_t	Markov Chain
L = 0	0	no
L = 0.5	0.5	no
L = 0.9	0.9	no
L = 0 (M)	0	yes
L = 0.5 (M)	0.5	yes
L = 0.9 (M)	0.9	yes
4 Ls	0, 0.5, 0.9	yes

Table 2: Cases.

State in $t - 1$	λ_t
WW	0
DW	0.5
WD	0.5
DD	0.9

Table 3: Lambda for each Markov state in case 4 Ls.

the model where λ_t can take different values depending on which of the four inflow states is realized in the previous stage. We use $L = 0, 0.5$, and 0.9 to represent risk neutrality, mild risk aversion, and strong risk aversion respectively. This gives seven models as shown in Table 2.

In the first three models we construct a candidate policy using SDDP under the assumption that inflows are stage-wise independent. In the second set of three models (denoted “(M)”) the policy is constructed using four Markov states. In the case “4 Ls”, λ_t takes three values as shown in Table 3.

In all cases we use the Markov chain inflow model to simulate the performance of the policy.

To validate our code, we first applied the seven risk settings to a model with $T = 4$ and 4 openings, giving a scenario tree with 64 scenarios. This allowed us to compare the lower bounds obtained with SDDP and the solution obtained from solving the deterministic equivalent linear program directly using CPLEX 11.0. The results, shown in Table 4, indicate that the algorithm performs as expected on small problems.

We now present the results of applying SDDP to the New Zealand problem for one year horizon with weekly time steps. In our implementation of SDDP, we use one scenario per iteration as discussed in Section 2). For each experiment we run SDDP for a maximum of 4000 iterations, except for case 7 where it is run for 16000 iterations so that each state has approximately 4000 cuts. As discussed above, when λ_t depends on the observed state in stage $t - 1$, we require more iterations to have similar number of cuts in each stage. Figure 6 depicts the lower bound for the first 4000 iterations of all cases 1-6 and 16000 iterations of case 7, which indicates that assuming convergence after having 4000 cuts seems to be reasonable.

Case	DLP Optimal Solution(10^6 \$)	Lower Bound (10^6 \$)
L = 0	6.5689816843	6.568981684267

L = 0	823.822
L = 0.5	643.570
L = 0.9	630.791
L = 0 (M)	631.020
L = 0.5 (M)	627.750
L = 0.9 (M)	628.265
4 Ls	628.273

Table 6: Most expensive scenario.

In order to compare the policies obtained in each case, we sampled 4000 inflow scenarios using the Markov chain, and tested the policies in each scenario. The results are presented in Table 5. Here the expected total operating cost measures fuel cost, shortage cost, and penalties for violating river flow constraints, in other words the risk-neutral objective function. Since case 4 (the risk-neutral Markov chain model) produces the smallest expected total operation cost, we list the increases in expected total operating cost of the other policies in the third column.

These numbers show several things. First of all, there is a small increase in expected cost (\$1.27M) from assuming stagewise independent inflows, when they are really Markovian. The SDDP model that assumes Markovian inflows should perform better in a benchmark simulation of these inflow sequences than a model that ignores this feature. The numbers also show the tradeoffs in expected cost that are incurred by an increase in risk aversion. As a percentage of the total cost, these numbers appear to be quite modest.

To investigate the potential benefits of the risk-averse models, we focus on some of the extreme scenarios that give large costs for the risk-neutral model. Table 6 gives the total operation cost in the worst case scenario for each policy. Case L = 0 (which is risk neutral and assumes independence) is substantially more expensive. It is interesting to see that a policy computed using Markov states, performs creditably in this worst case.

We can extend this examination to the 200 worst scenarios in each case represented by

Figure 7: Most expensive scenarios in the simulation.

the distributions of total cost shown in Figure 7. These plots represent the cumulative distribution functions of total cost under each policy, where the scenario counter references different scenarios for each plot, so they should not be interpreted as one policy uniformly dominating another over all scenarios. Nevertheless it is easy to see that the risk-neutral stage-wise independent model is stochastically dominated to first order by the other policies, at least over the 200 worst outcomes. The other policies seem to produce comparable distributions of total cost.

It is worth remarking that our multi-period risk measure ρ is not designed to control for total cost incurred over the year, and so the plots we show of total cost outcomes might mislead us. The exact interpretation of ρ (with $\lambda > 0$) is less obvious, but at any stage it controls high values of cost in the future, so the policy focuses on avoiding high future costs that might be incurred in the next few periods, whether they come from imminent shortages or the accumulated risk of a future shortage or constraint violation. This is arguably different from focusing on the distribution of total annual cost, and controlling the extent of its upper tail.

In addition to the most expensive cases of total cost we can examine the least expensive cases (corresponding to high inflows). Figure 8 depicts the least expensive total cost scenarios for each policy, in which one can notice that more risk averse policies incur higher costs when inflows are plentiful. This is reflected in Figure 9, which shows the expected national reservoir levels in terms of stored energy. Here one can observe that the risk averse policies save more water in the first half of the year to protect against low inflows later in the year. As a consequence, the risk averse models tend to use more thermal generation in the first half when might not be necessary and finish the year with reservoirs at higher levels than their

Figure 8: Least expensive scenarios in the simulation.

risk-neutral counterparts.

Many practical implementations of the LTHS problem make use of a reservoir danger zone or *minzone*. This is a trajectory of (possibly aggregate) reservoir storage that represents a minimum level for security of supply. Such a zone can be computed using simulation over future inflow sequences, and choosing a reservoir level that avoids shortages in a given high percentage of these sequences, assuming full commitment of all thermal plant. Once a minzone has been determined, penalty terms can be added to SDDP to discourage policies from allowing reservoir storage to enter the minzone.

Since we have chosen to ignore the New Zealand minzone in our model, it is interesting to see to what extent our model of risk aversion can prevent trajectories from passing into it. Figure 10 shows the number of scenarios that the national storage level was below the minzone in each stage. Both risk-neutral models were unable to avoid breaching the minzone in a large number of outcomes. The risk-averse models were more conservative, with only the $L = 0.5$ independent model showing some violation of the minzone.

We finish this section by studying the effect of risk aversion on load shedding (disconnecting consumers in times of shortage). Table 7 presents the probability of load shedding for each model, and its expected contribution to the cost. Both of these are very low in the risk-neutral cases, and zero for all risk-averse cases, although these figures are computed assuming a Markov inflow model, and may be substantially higher if inflows have a higher degree of stagewise dependence.

Figure 9: Expected national storage level in terms of energy.

Figure 10: Number of scenarios where the national storage level was below the minimum level.

Case	Risk of Load Shedding (%)	Expected Cost of Load Shedding (10^6 \$)
$L = 0$	0.085	0.421
$L = 0.5$	0	0
$L = 0.9$	0	0
$L = 0$ (M)	0.025	0.0005
$L = 0.5$ (M)	0	0
$L = 0.9$ (M)	0	0
4 Ls	0	0

Table 7: Risk and Expected cost of Load Shedding.

7 Conclusions

It appears from our limited experiments that risk aversion can be incorporated into multi-stage models with surprising ease. Given an appropriate level of risk aversion it is possible to reduce the probability of bad outcomes with only mild degradation in overall cost. In our experiments we chose λ_t to take the same value L throughout the year. Varying λ_t throughout the year to be low at times when inflows and reservoir levels are typically high, and high otherwise is likely to yield improvements in performance, but we have not attempted this here, as these choices are problem dependent, and settings obtained for the New Zealand system would be unlikely to apply generally.

The risk-averse methodology we have described provides a promising alternative to the use of minzones for controlling risk. In SDDP it is impossible to impose minzones as hard constraints, because that will violate the assumption of relatively complete recourse. For this reason soft constraints with violation penalties are preferred. However it is often not obvious what penalties one should place on minzone violations to give appropriate safeguards. When a real constraint is actually violated (for example when load must be shed) the costs incurred are also real, rather than penalties used to control risk, and so they are easier to justify even though they may be challenging to estimate. Moreover, since each stage problem can be a relatively large linear program, naive choices of these penalties can give counterintuitive results. For example, one would not want to shed load in order to meet a minzone constraint, which might happen with a poor choice of penalties. Our results show that with appropriate choices of λ_t , a dynamic risk measure can meet constraints with very high probability with a modest increase in expected operation cost.

A potential weakness with our approach is the difficulty in estimating the value of a candidate policy. This value can be interpreted as an equivalent payment we would make in any state to avoid incurring future costs. However, even without this estimate, we can still estimate parameters for the distributions of parameters of interest. We see that risk-averse models are performing as expected, by saving more water in the reservoirs, reducing the costs in the most expensive scenarios and reducing the risk of load shedding. As expected, the system has to pay a price for the risk aversion, which is a function of the risk aversion level.
