Worst-case evaluation complexity of regularization methods for smooth unconstrained optimization using Hölder continuous gradients

C. Cartis[*] N. I. M. Gould[†] and Ph. L. Toint[‡]

26 June 2015

Abstract

The worst-case behaviour of a general class of regularization algorithms is considered in the case where only objective function values and associated gradient vectors are evaluated. Upper bounds are derived on the number of such evaluations that are needed for the algorithm to produce an approximate first-order critical point whose accuracy is within a user-defined threshold. The analysis covers the entire range of meaningful powers in the regularization term as well as in the Hölder exponent for the gradient. The resulting complexity bounds vary according to the regularization power and the assumed Hölder exponent, recovering known results when available.

1 Introduction

The complexity analysis of algorithms for smooth, possibly non-convex, unconstrained optimization has been the subject of a burgeoning literature over the past few years (see the contributions by Nesterov [12, 15], Gratton, Sartenaer and Toint [11], Cartis, Gould and Toint [3, 5, 6, 7], Ueda [17], Ueda and Yamashita[18, 19], Grapiglia, Yuan and Yuan [9, 10], and Vicente [20], for instance). The present contribution belongs to this active trend and focuses on the analysis of the worst-case behaviour of regularization methods where only objective function values and associated gradient vectors are evaluated. It proposes upper bounds on the number of such evaluations that are needed for the algorithm to produce an approximate first-order critical point whose accuracy is within a user-defined threshold.

An analysis of this type is already available for the case where the objective function's gradient is assumed to be Lipschitz-continuous and where the regularization uses the second or third power of the norm of the computed step at a given iteration (see the paper by Nesterov [13] for the former and those of Cartis *et al.* [5, 6] for both cases). The novelty of the present approach is to extend the analysis to cover problems whose objective gradients are simply Hölder continuous and methods that allow weaker regularization than in the Lipschitz case.

1

The resulting complexity bounds vary according to the regularization power and the assumed Hölder exponent, providing a unified view and recovering known results when available.

The paper is organized as follows. Section 2 presents the problem and the class of algorithms considered. The complexity analysis itself is given in Section 3 and the sharpness of the obtained result is discussed in Section 4. Section 5 finally provides some comments of the results.

Notations: In what follows, $\| \cdot \|$ denotes the Euclidean norm and the ^{T} superscript denotes transposition. If v is a vector in $\mathbb{R}^n$, $[v]_i$ denotes its i-th component.

2 The problem and algorithm

We consider the problem of finding an approximate solution of the optimization problem

$$\min_x f(x) \tag{2.1}$$

where $x \in \mathbb{R}^n$ is the vector of optimization variables and f is a function from $\mathbb{R}^n$ into $\mathbb{R}$ that is assumed to be bounded below and continuously differentiable with Hölder continuous gradients. If we denote $g(x) \stackrel{\text{def}}{=} \nabla_x f(x)$, the latter says that the inequality

$$\|g(x) - g(y)\| \le L_\beta \|x - y\|^\beta \tag{2.2}$$

holds for all $x, y \in \mathbb{R}^n$, where $L_\beta \ge 0$ and $\beta > 0$ are constants independent of x and y and where $\| \cdot \|$ is the Euclidean norm on $\mathbb{R}^n$. As explained in Lemma 3.1 below, we will assume, without loss of generality, that $\beta \le 1$. Problems involving functions with Hölder continuous gradients are interesting on their own rights, but can also be found in engineering practice, such as in the design of gas pipelines (the Panhandle law which governs such flows states that the gas flow rate in a pipeline is a power between 1 and 2 of the difference in squared pressures, see [16, Section 17], for instance). Such functions also appear in the solution of certain nonlinear PDE problems (see Bensoussan and Frehse [1]).

In our context, an approximate solution for problem (2.1) is a vector x_ϵ such that

$$\|g(x_\epsilon)\| \le \epsilon \quad \text{or} \quad f(x) \le f_{\text{target}} \tag{2.3}$$

where $\epsilon > 0$ is a user-specified accuracy threshold and f_{target} is a threshold value – independent of ϵ – under which the reduction of the objective function is deemed sufficient by the user. The first case in (2.3) corresponds to finding an approximate first-order-critical point. If a suitable value for f_{target} is not known, minus infinity can be used instead, in effect making the second part of (2.3) impossible to satisfy and reducing this condition to its first part.

The class of regularization methods that we consider for computing an x satisfying (2.3) consists of iterative algorithms where, at each iteration, a local (linear or quadratic) model of f around the current iterate x_k is constructed, regularized by a term using the p-th power of the norm of the step, and then approximately minimized (in the "Cauchy point" sense) to provide a trial step s_k. The quality of this step is then measured in order to accept the resulting trial point $x_k + s_k$ as the next iterate, or to reject it and adjust the strength of the regularization.

More specifically, a regularized model of $f(x_k + s)$ of the form

$$m_k(x_k + s) = f(x_k) + g_k^T s + \tfrac{1}{2} s^T B_k s + \frac{\sigma_k}{p} \|s\|^p \tag{2.4}$$

is considered around the k-th iterate x_k, where we have defined $g_k \stackrel{\text{def}}{=} g(x_k)$, where B_k is a symmetric $n \times n$ matrix, where $\sigma_k > 0$ is the regularization parameter at iteration k and where $p > 1$ is the (iteration independent) user-defined regularization power. In practice, the matrix B_k may be chosen to provide suitable scaling of the variables (if known), for instance using quasi-Newton formulae. The model (2.4) is then approximately minimized in the sense that the trial step s_k is computed such that

$$m_k(x_k + s_k) \le m_k(x_k + s_k^C), \tag{2.5}$$

where the "Cauchy step" s_k^C is defined by

$$s_k^C = -\alpha_k^C g_k \ \ \text{with} \ \ \alpha_k^C = \arg\min_{\alpha \ge 0} m_k(x_k - \alpha g_k). \tag{2.6}$$

We will choose the regularization power p in (2.4) in order to guarantee that m_k is bounded below and grows at infinity, thereby ensuring that (2.6) is well-defined. In particular, this imposes the restriction $p > 1$ and furthermore

$$p > 2 \ \ \text{whenever } B_k \text{ is allowed to not be positive semi-definite.} \tag{2.7}$$

Notice that (2.5) and (2.6) together imply that

$$m_k(x_k + s_k) \le m_k(x_k + s_k^C) < f(x_k) \tag{2.8}$$

provided $g(x_k) \neq 0$. We may now describe our class of algorithms more formally as Algorithm 2.1 on the following page.

Iterations of Algorithm 2.1 where $\rho_k \ge \eta_1$ are called "successful" and their index set is denoted by $\mathcal{S}$. Note that the mechanism of the algorithm ensures that $\sigma_k > 0$ for all $k \ge 0$. Note also that each iteration of the algorithm involves a single evaluation of the objective function and (for successful iterations only) of its gradient. The evaluation complexity can therefore be carried out by measuring how many *iterations* are needed before an approximate first-order critical point is found or the objective value decreases below the required target.

If $p = 2$ or $p = 3$, the model minimization occuring in Step 2 of the algorithm is typically easy to compute if one is happy with the minimum requirement that (2.5) and (2.6) hold: an efficient unidimensional linesearch technique using quadratic or cubic interpolation is all that is needed. Larger model decrease may be obtained by pursuing the minimization beyond the Cauchy point, and again efficient algorithms are known for quadratic and cubic regularizations (see Cartis *et al.* [4] for the latter case, the former being the well known problem of minimizing a quadratic function). Good methods are also available for more general values of p (in effect requiring the one-dimensional minimization of a p-th order polynomial) : see Cartis *et al.* [2] for the case of regularized least-norm problems with general $p \ge 2$ or Gould, Robinson and Thorne [8] for even more general cases.

3 Worst-case evaluation complexity analysis

In order to analyze the worst-case complexity of Algorithm 2.1, we need to specify our assumptions.

Algorithm 2.1: A Class of First-Order Adaptive Regularization Methods

Step 0: Initialization. An initial point x_0 , a target objective function value $f_{\text{target}} \leq f(x_0)$ and an initial regularization parameter $\sigma_0 > 0$ are given, as well as an accuracy level ϵ. The constants η_1, η_2, γ_1, γ_2 and γ_3 are also given and satisfy

$$0 < \eta_1 \leq \eta_2 < 1 \text{ and } 0 < \gamma_1 < 1 < \gamma_2 < \gamma_3. \tag{2.9}$$

Compute $f(x_0)$ and set $k = 0$.

Step 1: Test for termination. If $\|g_k\| \leq \epsilon$ or $f(x_k) \leq f_{\text{target}}$, terminate with the approximate solution $x_\epsilon = x_k$.

Step 2: Step calculation. Compute the step s_k approximately by minimizing the model (2.4) in the sense that conditions (2.5) and (2.6) hold.

Step 3: Acceptance of the trial point. Compute $f(x_k + s_k)$ and define

$$\rho_k = \frac{f(x_k) - f(x_k + s_k)}{m_k(x_k) - m_k(x_k + s_k)}. \tag{2.10}$$

If $\rho_k \geq \eta_1$, then define $x_{k+1} = x_k + s_k$ and evaluate $g(x_{k+1})$; otherwise define $x_{k+1} = x_k$.

Step 4: Regularization parameter update. Set

$$\sigma_{k+1} \in \begin{cases} [\gamma_1 \sigma_k, \sigma_k] & \text{if } \rho_k \geq \eta_2, \\ [\sigma_k, \gamma_2 \sigma_k] & \text{if } \rho_k \in [\eta_1, \eta_2), \\ [\gamma_2 \sigma_k, \gamma_3 \sigma_k] & \text{if } \rho_k < \eta_1. \end{cases} \tag{2.11}$$

Increment k by one and go to Step 1.

AS.1 The objective function f is continuously differentiable on $\mathbb{R}^n$.

AS.2 $g = \nabla_x f$ is Hölder continuous in the sense that (2.2) holds for all $x, y \in \mathbb{R}^n$ and some constants $L_\beta \geq 0$ and $\beta > 0$.

AS.3 There exists a constant f_{low} (possibly equal to minus infinity) such that, for all $x \in \mathbb{R}^n$,

$$f(x) \geq f_{\text{low}} \quad \text{and} \quad f_* \overset{\text{def}}{=} \max[f_{\text{low}}, f_{\text{target}}] > -\infty$$

AS.4 There exists constants $\kappa_{gl} \geq 0$ and $\kappa_{gu} \geq 1$ such that

$$\kappa_{gl} \leq \|g(x)\| \leq \kappa_{gu} \text{ for all } x \in \mathbb{R}^n \text{ such that } f_* \leq f(x) \leq f(x_0).$$

AS.5 There exists a constant $\kappa_B \geq 0$ such that, for all $k \geq 0$,

$$\|B_k\| \leq \kappa_B.$$

AS.1 and AS.2 formalize our framework, as described in the introduction while AS.5 is standard in similar contexts and avoids possibly infinite curvature of the model, which would make the regularization irrelevant. Note that the values of $L_\beta \geq 0$ and $\beta > 0$ are often unknown to the user. AS.3 states that, if no target value is specified by the user, then there must exist a global lower bound on the objective function's values to make the minimization problem meaningful. The role of AS.4 is to take into account that, when $f_* = f_{\text{target}} > f_{\text{low}}$, it may well happen that no single $x \in \mathbb{R}^n$ satisfies both conditions in (2.3), and thus that the first termination criterion in (2.3) cannot be satisfied by our minimization algorithm before the second. We take this possibility into account by allowing $\kappa_{gl} > 0$, and expresssing the complexity results in terms of

$$\epsilon_* \stackrel{\text{def}}{=} \max[\epsilon, \kappa_{gl}] \tag{3.1}$$

which is the "attainable" gradient accuracy for the problem given f_{target}. For simplicity of exposition, we assume for now that $\epsilon_* < 1$, but comment on the case $\epsilon_* \geq 1$ at the end of the paper. We note that AS.4 automatically holds if the set $\{x \in \mathbb{R}^n \mid f_* \leq f(x) \leq f(x_0)\}$ is bounded, but also, as we discuss in Lemma 3.2 below, in the frequent situation where $f(x)$ is bounded below on the level set $\{x \in \mathbb{R}^n \mid f(x) \leq f(x_0)\}$.

We start by deriving consequences of our assumptions, which are independent of the algorithm. The first is intended to explore the consequence of a value of β exceeding 1.

Lemma 3.1 Suppose that AS.1 holds and that AS.2 holds for some $\beta > 1$. Then f is linear in $\mathbb{R}^n$, AS.2 holds for all $\beta > 0$ with $L_\beta = 0$ and AS.4 holds with $\kappa_{gl} = \kappa_{gu} = \|g(x_0)\|$.

Proof. If e_i is the i-th vector of the canonical basis and $[g(x)]_i$ the i-th component of the gradient at x, we have, using the Cauchy-Schwarz inequality and the Hölder condition (2.2), that, for all $i = 1, \ldots, n$ and all $x \in \mathbb{R}^n$,

$$\frac{|[g(x + te_i)]_i - [g(x)]_i|}{|t|} \leq \frac{\|g(x + te_i) - g(x)\|}{\|x + te_i - x\|} \leq L_\beta |t|^{\beta-1}$$

and $\beta - 1 > 0$. Taking the limit when $t \to 0$ gives that the directional derivative of each $[g(\cdot)]_i$ exists and is zero for all i and at all x. Thus the gradient is constant in $\mathbb{R}^n$, f is linear and AS.2 obviously holds with $L_\beta = 0$ for all $\beta > 0$ since $\|g(x) - g(y)\|$ is identically zero for all $x, y \in \mathbb{R}^n$. □

This justifies our choice to restrict our attention to the case where $\beta \in (0, 1]$ for the rest of our analysis. The second result indicates common circumstances in which AS.4 holds.

Lemma 3.2 Suppose that AS.1 and AS.2 hold, and that there exists a constant $f_{\text{low}} > -\infty$ such that

$$f(x) \geq f_{\text{low}} \tag{3.2}$$

for all $x \in \mathcal{L}_0 \stackrel{\text{def}}{=} \{x \in \mathbb{R}^n \mid f(x) \leq f(x_0)\}$ for all $x \in \mathbb{R}^n$. Then AS.4 holds.

Proof. Let $x \in \mathcal{L}_0$. AS.1, the mean-value theorem, and AS.2 then ensure that, for all s,

$$
\begin{aligned}
f_{\text{low}} \quad &\leq \quad f(x + s) \\[2mm]
&\leq \quad f(x) + g(x)^T s + \int_0^1 (g(x + \xi s) - g(x))^T s \, d\xi \\[2mm]
&\leq \quad f(x) + g(x)^T s + \frac{L_\beta}{1 + \beta} \|s\|^{\beta+1} \stackrel{\text{def}}{=} h(s)
\end{aligned}
\tag{3.3}
$$

Given that the minimizer of the convex function $h(s)$ is given by

$$
s_* = -\frac{g(x)}{L_\beta^{1/\beta}} \|g(x)\|^{\frac{1-\beta}{\beta}},
$$

we obtain that

$$
\min_s h(s) = h(s_*) = f(x) - \frac{\beta \, L_\beta^{-\frac{1}{\beta}}}{1 + \beta} \|g(x)\|^{1+\frac{1}{\beta}}.
$$

As a consequence, we obtain, using the fact that $f(x) \leq f(x_0)$ since $x \in \mathcal{L}_0$ and (3.3), that

$$
f_{\text{low}} \leq f(x_0) - \frac{\beta \, L_\beta^{-\frac{1}{\beta}}}{1 + \beta} \|g(x)\|^{1+\frac{1}{\beta}},
$$

which in turn implies that

$$
\|g(x)\| \leq \left[L_\beta \left(1 + \frac{1}{\beta}\right)^\beta (f(x_0) - f_{\text{low}})^\beta \right]^{\frac{1}{1+\beta}} \stackrel{\text{def}}{=} \kappa_{gu},
$$

irrespective of the value of f_{target}. This and the choice $\kappa_{gl} = 0$ yield the desired conclusion.
□

Note that (3.2) is indeed very common. For instance, $f_{\text{low}} = 0$ for all nonlinear least-squares problems. Hence the form of AS.4 should not be viewed as overly restrictive and also allows for the case where (3.2) fails but the objective function's gradient remains reasonably well-behaved. For instance, problems whose objective function is an indefinite quadratic are allowed provided $f_{\text{target}} > -\infty$.

We now turn to the analysis of the algorithm's properties. But, before we start in earnest, it is useful to introduce some specific notation. In a number of occurrences, we need to include some of the terms in formulae only if certain conditions apply. We will indicate this by underbracing the conditional part of the formula, the text below the underbrace then specifying the relevant condition. For instance we may have an expression of the type

$$
\max[\underbrace{a^{-1}}_{a>0}, b, c],
$$

meaning that the maximum should include the first term if and only if $a > 0$ (making the term well-defined in this case).

We first derive two bounds of the step length, generalizing Lemma 2.2 in [4].

Lemma 3.3 We have that, for all $k \geq 0$,

$$\|s_k\| \leq \max\left[\underbrace{\left(\frac{p}{\sigma_k}\|B_k\|\right)^{\frac{1}{p-2}}}_{B_k \not\geq 0}, \left(\frac{2p}{\sigma_k}\|g_k\|\right)^{\frac{1}{p-1}} \right]. \tag{3.4}$$

Moreover,

$$\|s_k\| \leq \left(\frac{2p}{\sigma_k}\|g_k\|\right)^{\frac{1}{p-1}} \tag{3.5}$$

provided

$$\sigma_k \geq \frac{(p\|B_k\|)^{p-1}}{(2p\|g_k\|)^{p-2}}. \tag{3.6}$$

Proof. Observe first that (2.4), (2.8) and $g_k \neq 0$ ensure that

$$m_k(x_k + s_k) - f(x_k) = g_k^T s_k + \tfrac{1}{2}s_k^T B_k s_k + \frac{\sigma_k}{p}\|s_k\|^p < 0 \tag{3.7}$$

Assume first that $s_k^T B_k s_k > 0$. Then we must have that

$$g_k^T s_k + \frac{\sigma_k}{p}\|s_k\|^p < 0,$$

and therefore (remembering that $\sigma_k > 0$ and that $g_k^T s_k \geq -\|g_k\|\,\|s_k\|$)

$$\|s_k\| < \left(\frac{p}{\sigma_k}\|g_k\|\right)^{\frac{1}{p-1}} < \left(\frac{2p}{\sigma_k}\|g_k\|\right)^{\frac{1}{p-1}}. \tag{3.8}$$

If $s_k^T B_k s_k \leq 0$, we may rewrite (3.7) as

$$\left[g_k^T s_k + \frac{\sigma_k}{2p}\|s_k\|^p\right] + \left[\tfrac{1}{2}s_k^T B_k s_k + \frac{\sigma_k}{2p}\|s_k\|^p\right] < 0$$

and the left-hand side of this inequality can only be negative if at least one of the bracketed expressions is negative, giving that

$$\|s_k\| \leq \max\left[\left(\frac{p}{\sigma_k}\|B_k\|\right)^{\frac{1}{p-2}}, \left(\frac{2p}{\sigma_k}\|g_k\|\right)^{\frac{1}{p-1}} \right],$$

where we also used that $g_k^T s_k \geq -\|g_k\|\,\|s_k\|$ and $s_k^T B_k s_k \geq -\|B_k\|\,\|s_k\|^2$. Combining this with (3.8) then yields (3.4). Checking (3.5) subject to (3.6) is straightforward. $\square$

We now turn to the task of finding a lower bound on the model decrease $f(x_k) - m_k(x_k + s_k)$ resulting from (2.5)-(2.6). The first step is to find a suitable positive lower bound on the step α_k^C as defined in (2.6).

Lemma 3.4 We have that

$$m_k(x_k + s_k^C) \le m_k(x_k - \alpha_k^* g_k) < f(x_k) \tag{3.9}$$

where

$$\alpha_k^* \overset{\text{def}}{=} \min\left[\underbrace{\frac{\|g_k\|^2}{2 g_k^T B_k g_k}}_{g_k^T B_k g_k > 0}, \left(\frac{p}{2\sigma_k} \frac{1}{\|g_k\|^{p-2}} \right)^{\frac{1}{p-1}} \right] \tag{3.10}$$

Proof.   Substituting the definition $s = -\alpha g_k$ into (2.4), we obtain from (2.5)-(2.6) that, for all $\alpha > 0$,

$$m_k(x_k - \alpha g_k) - f(x_k) = \alpha\left(-\|g_k\|^2 + \tfrac{1}{2}\alpha g_k^T B_k g_k + \frac{\sigma_k}{p}\alpha^{p-1}\|g_k\|^p \right). \tag{3.11}$$

Assume first that $g_k^T B_k g_k \le 0$. Then

$$-\|g_k\|^2 + \frac{\sigma_k}{p}\alpha^{p-1}\|g_k\|^p < 0$$

for all $\alpha \in (0, \bar\alpha_k]$ where

$$\bar\alpha_k = \left(\frac{p}{\sigma_k} \frac{1}{\|g_k\|^{p-2}} \right)^{\frac{1}{p-1}} \tag{3.12}$$

and, because $\alpha > 0$ and $g_k^T B_k g_k \le 0$, we also obtain from (3.11) that $m_k(x_k - \alpha g_k) < f(x_k)$ for all $\alpha \in (0, \bar\alpha_k]$. In particular, this yields that $m_k(x_k - \alpha_k^* g_k) < f(x_k)$, where

$$\alpha_k^* = \left(\frac{p}{2\sigma_k} \frac{1}{\|g_k\|^{p-2}} \right)^{\frac{1}{p-1}}. \tag{3.13}$$

Condition (2.6) then ensures that (3.9) holds as desired.

Assume next that $g_k^T B_k g_k > 0$ and, in this case, define

$$\alpha_k^* \overset{\text{def}}{=} \min\left[\frac{\|g_k\|^2}{2 g_k^T B_k g_k}, \left(\frac{p}{2\sigma_k} \frac{1}{\|g_k\|^{p-2}} \right)^{\frac{1}{p-1}} \right]$$

Then it is easy to verify that both bracketed expressions in

$$\left[-\tfrac{1}{2}\|g_k\|^2 + \tfrac{1}{2}\alpha_k^* g_k^T B_k g_k \right] + \left[-\tfrac{1}{2}\|g_k\|^2 + \frac{\sigma_k}{p}(\alpha_k^*)^{p-1}\|g_k\|^p \right] = \frac{1}{\alpha_k^*}\left(m_k(x_k - \alpha_k^* g_k) - f(x_k) \right)$$

are negative and thus, because $\alpha_k^* > 0$, that $m_k(x_k - \alpha_k^* g_k) < f(x_k)$. The desired conclusion can now be obtained by invoking (2.6).   □

We now translate the conclusions of the last lemma in terms of the model reduction at the Cauchy point and beyond, generalizing Lemma 2.1 in [4].

Lemma 3.5 We have that

$$f(x_k) - m_k(x_k + s_k) \geq \frac{1}{4} \min \left[\underbrace{\frac{\|g_k\|^4}{2g_k^T B_k g_k}}_{g_k^T B_k g_k > 0}, \left(\frac{p}{2\sigma_k} \|g_k\|^p \right)^{\frac{1}{p-1}} \right]. \tag{3.14}$$

Proof.   If $g_k^T B_k g_k \leq 0$, substituting (3.13) into (3.11) immediately yields that

$$f(x_k) - m_k(x_k - \alpha_k^* g_k) \geq \left(\frac{p}{2\sigma_k} \frac{1}{\|g_k\|^{p-2}} \right)^{\frac{1}{p-1}} \left[\|g_k\|^2 - \tfrac{1}{2}\|g_k\|^2 \right] = \frac{1}{2} \left(\frac{p}{2\sigma_k} \|g_k\|^p \right)^{\frac{1}{p-1}}. \tag{3.15}$$

If $g_k^T B_k g_k > 0$, we have from (3.11) and (3.10) that

$$f(x_k) - m_k(x_k - \alpha_k^* g_k)$$

$$\geq \ \alpha_k^* \left[\|g_k\|^2 - \frac{1}{2} \left(\frac{\|g_k\|^2}{2g_k^T B_k g_k} \right) g_k^T B_k g_k - \frac{\sigma_k}{p} \left(\frac{p}{2\sigma_k} \frac{1}{\|g_k\|^{p-2}} \right) \|g_k\|^p \right]$$

$$= \ \min \left[\frac{\|g_k\|^2}{2g_k^T B_k g_k}, \left(\frac{p}{2\sigma_k} \frac{1}{\|g_k\|^{p-2}} \right)^{\frac{1}{p-1}} \right] \left[\|g_k\|^2 - \tfrac{1}{4}\|g_k\|^2 - \tfrac{1}{2}\|g_k\|^2 \right]$$

$$= \ \frac{1}{4} \min \left[\frac{\|g_k\|^4}{2g_k^T B_k g_k}, \left(\frac{p}{2\sigma_k} \|g_k\|^p \right)^{\frac{1}{p-1}} \right].$$

Combining this last inequality with (3.15) and using (2.5) then gives (3.14).   □

The model decrease specified by (3.14) turns out to be useful if the value of σ_k (appearing at the denominator of the second term in the min) can be bounded above across all iterations. We obtain this result in two stages, the first being to determine conditions under which an iteration must be very successful.

Lemma 3.6 Suppose that AS.1, AS.2 and AS.5 hold. Then $\rho_k \geq \eta_2$, iteration k is very successful and $\sigma_{k+1} \leq \sigma_k$

(i) if $1 + \beta \geq p$ and

$$\sigma_k \geq \kappa_1 \|g_k\|^{\frac{1+\beta-p}{\beta}} \tag{3.16}$$

where

$$\kappa_1 \overset{\text{def}}{=} 2p \left(\frac{L_\beta}{1+\beta} \right)^{\frac{p-1}{\beta}},$$

(ii) if $1 + \beta < p$ and

$$\sigma_k \geq \kappa_2 \max \left[\|g_k\|^{2-p}, \|g_k\|^{\frac{1+\beta-p}{\beta}} \right] \tag{3.17}$$

where

$$\kappa_2 \overset{\text{def}}{=} \max \left[2p \left(2\kappa_B \right)^{p-1}, \, 2^{\frac{2+\beta}{\beta}} p \kappa_3^{\frac{1}{\beta}}, 8p\kappa_3 \right] \tag{3.18}$$

with

$$\kappa_3 \overset{\text{def}}{=} \left(\left[\frac{L_\beta}{1+\beta} + \tfrac{1}{2}\kappa_B \right] \left[\frac{4}{1-\eta_2} \right] \right)^{p-1}. \tag{3.19}$$

Proof.   First notice that AS.1, the mean-value theorem and (2.4) imply that

$$f(x_k + s_k) - m_k(x_k + s_k) = \int_0^1 (g(x_k + \xi s_k) - g_k)^T s_k \, d\xi - \tfrac{1}{2}s_k^T B_k s_k - \frac{\sigma_k}{p}\|s_k\|^p.$$

Using now AS.2, we obtain that

$$f(x_k + s_k) - m_k(x_k + s_k) \leq \frac{L_\beta}{1+\beta}\|s_k\|^{1+\beta} - \tfrac{1}{2}s_k^T B_k s_k - \frac{\sigma_k}{p}\|s_k\|^p. \tag{3.20}$$

Assume first that $p \leq 1+\beta$ (which implies that $B \succeq 0$ because of (2.7)). Then $f(x_k+s_k) \leq m_k(x_k + s_k)$ (and thus $\rho_k \geq 1 > \eta_2$) if

$$\sigma_k \geq \frac{pL_\beta}{1+\beta}\|s_k\|^{1+\beta-p},$$

which, in view of (3.4) and $B_k \succeq 0$, holds if

$$\sigma_k \geq \frac{pL_\beta}{1+\beta} \left(\frac{2p}{\sigma_k}\|g_k\| \right)^{\frac{1+\beta-p}{p-1}},$$

that is if

$$\sigma_k \geq 2p \left(\frac{L_\beta}{1+\beta} \right)^{\frac{p-1}{\beta}} \|g_k\|^{\frac{1+\beta-p}{\beta}}, \tag{3.21}$$

proving the first item in the lemma's statement.

Assume now that $p > 1 + \beta$, in which case B_k is allowed to be indefinite if $p > 2$ and we cannot guarantee that $s_k^T B_k s_k \geq 0$ in (3.20). Then $\rho_k \geq \eta_2$ if

$$r_k \stackrel{\text{def}}{=} f(x_k + s_k) - m_k(x_k + s_k) - (1 - \eta_2)(f(x_k) - m_k(x_k + s_k)) < 0.$$

Note that a lower bound on $f(x_k) - m_k(x_k + s_k)$ is given by Lemma 3.5. If we now assume that, whenever $g_k^T B_k g_k > 0$,

$$\sigma_k \geq \frac{p}{2}(2\kappa_B)^{p-1} \|g_k\|^{2-p}, \tag{3.22}$$

then we obtain that the minimum occurring in the right-hand side of (3.14) is achieved by the second term, yielding that

$$f(x_k) - m_k(x_k + s_k) \geq \frac{1}{4}\left(\frac{p}{2\sigma_k}\|g_k\|^p\right)^{\frac{1}{p-1}}.$$

As a consequence, we obtain from (3.20), the Cauchy-Schwarz inequality and AS.5 that

$$r_k \leq \frac{L_\beta}{1+\beta}\|s_k\|^{1+\beta} + \tfrac{1}{2}\kappa_B\|s_k\|^2 - \frac{1-\eta_2}{4}\left(\frac{p}{2\sigma_k}\|g_k\|^p\right)^{\frac{1}{p-1}}.$$

If we also assume that, whenever $B_k \not\succeq 0$, (3.6) also holds, then we may substitute the upper bound (3.5) in this equation and obtain that $r_k < 0$ if

$$\frac{L_\beta}{1+\beta}\left(\frac{2p}{\sigma_k}\|g_k\|\right)^{\frac{1+\beta}{p-1}} + \tfrac{1}{2}\kappa_B\left(\frac{2p}{\sigma_k}\|g_k\|\right)^{\frac{2}{p-1}} < \frac{1-\eta_2}{4}\left(\frac{p}{2\sigma_k}\|g_k\|^p\right)^{\frac{1}{p-1}}.$$

Now, if, on one hand,

$$\left(\frac{2p}{\sigma_k}\|g_k\|\right)^{\frac{1+\beta}{p-1}} \geq \left(\frac{2p}{\sigma_k}\|g_k\|\right)^{\frac{2}{p-1}}, \tag{3.23}$$

then we obtain that $r_k < 0$ if

$$\left(\frac{L_\beta}{1+\beta} + \tfrac{1}{2}\kappa_B\right)\left(\frac{2p}{\sigma_k}\|g_k\|\right)^{\frac{1+\beta}{p-1}} < \frac{1-\eta_2}{4}\left(\frac{p}{2\sigma_k}\|g_k\|^p\right)^{\frac{1}{p-1}}.$$

Taking the $(p-1)$-th power and rearranging, we obtain that $r_k < 0$ if

$$\sigma_k \geq 2^{\frac{2+\beta}{\beta}}p\left(\frac{L_\beta}{1+\beta} + \tfrac{1}{2}\kappa_B\right)^{\frac{p-1}{\beta}}\left(\frac{4}{1-\eta_2}\right)^{\frac{p-1}{\beta}}\|g_k\|^{\frac{1+\beta-p}{\beta}}. \tag{3.24}$$

If, on the other hand, (3.23) fails, then $r_k < 0$ if

$$\left(\frac{L_\beta}{1+\beta} + \tfrac{1}{2}\kappa_B\right)\left(\frac{2p}{\sigma_k}\|g_k\|\right)^{\frac{2}{p-1}} < \frac{1-\eta_2}{4}\left(\frac{p}{2\sigma_k}\|g_k\|^p\right)^{\frac{1}{p-1}}.$$

Once more taking the $(p-1)$-th power and rearranging, we obtain that $r_k < 0$ if

$$\sigma_k \geq 8p\left(\frac{L_\beta}{1+\beta} + \tfrac{1}{2}\kappa_B\right)^{p-1}\left(\frac{4}{1-\eta_2}\right)^{p-1}\|g_k\|^{2-p}. \tag{3.25}$$

Thus $r_k < 0$ (and therefore $\rho_k \geq \eta_2$) when $p > 1 + \beta$ provided (3.24) and (3.25) hold together with (3.6) (when $B_k \npreceq 0$) and (3.22) (when $g_k^T B_k g_k > 0$). This proves the second item in the lemma's statement if we note that

$$\frac{(p\kappa_B)^{p-1}}{(2p)^{p-2}} = 2p\left(\frac{1}{2}\kappa_B\right)^{p-1} < 2p\left(2\kappa_B\right)^{p-1} \quad \text{and} \quad \frac{p}{2}(2\kappa_B)^{p-1} < 2p\left(2\kappa_B\right)^{p-1}.$$

$\square$

Note that the second part of the lemma extends the result of Lemma 3.1 in [5] to general p and β. We are now in position to prove an iteration-independent upper bound on the value of σ_k.

Lemma 3.7 Suppose that AS.1–AS.5 hold and that $\epsilon_* < 1$. Then, as long as the algorithm does not terminate, we have that, for all $k \geq 0$,

(i) if $1 + \beta \geq p$,

$$\sigma_k \leq \kappa_1^\sigma, \tag{3.26}$$

where

$$\kappa_1^\sigma \overset{\text{def}}{=} \max\left[\gamma_3 \kappa_1 \kappa_{gu}^{1+\beta-p}, \sigma_0\right] \tag{3.27}$$

(ii) if $1 + \beta < p$,

$$\sigma_k \leq \max\left[\kappa_2^\sigma, \kappa_3^\sigma \epsilon_*^{\frac{1+\beta-p}{\beta}}\right], \tag{3.28}$$

where

$$\kappa_2^\sigma \overset{\text{def}}{=} \max\left[0, \underbrace{\gamma_3 \kappa_2 \kappa_{gu}^{2-p}}_{p \leq 2}, \sigma_0\right] \quad \text{and} \quad \kappa_3^\sigma \overset{\text{def}}{=} \gamma_3 \kappa_2. \tag{3.29}$$

with κ_1 and κ_2 defined in (3.18).

Proof. We again distinguish two cases. Assume first that $1 + \beta \geq p$, which in turn implies that $p \in (1, 2]$ and thus, in view of (2.7), that $B_k \succeq 0$ for all k. Then AS.4 and condition Lemma 3.6 (i) imply that $\sigma_{k+1} \leq \sigma_k$ provided

$$\sigma_k \geq \kappa_1 \kappa_{gu}^{\frac{1+\beta-p}{\beta}}, \tag{3.30}$$

which is a constant independent of k and ϵ.

The second case is when $1 + \beta < p$. We first consider the subclass where $p \leq 2$ where, using AS.4,

$$\|g_k\|^{2-p} \leq \kappa_{gu}^{2-p}. \tag{3.31}$$

This bound, part (ii) of Lemma 3.6 and the fact that $\|g_k\| > \epsilon_*$ as long as the algorithm has not terminated then imply that $\sigma_{k+1} \leq \sigma_k$ provided

$$\sigma_k \geq \kappa_2 \max\left[\underbrace{\kappa_{gu}^{2-p}}_{p \leq 2}, \epsilon_*^{\frac{1+\beta-p}{\beta}}\right] \tag{3.32}$$

where we have used that $1 + \beta - p < 0$. Alternatively, if $p > 2$, part (ii) of Lemma 3.6 and the fact that $\|g_k\| > \epsilon_*$ as long as the algorithm has not terminated then give that $\sigma_{k+1} \leq \sigma_k$ provided

$$\sigma_k \geq \kappa_2 \max \left[\epsilon_*^{2-p}, \epsilon_*^{\frac{1+\beta-p}{\beta}} \right] = \kappa_2 \epsilon_*^{\frac{1+\beta-p}{\beta}}, \tag{3.33}$$

where the last equality now results from the fact that , because $\beta \leq 1$,

$$0 > 2 - p \geq \frac{2-p}{\beta} \geq \frac{1+\beta-p}{\beta}.$$

The proof of (3.26) and (3.28) is then completed by taking into account that the initial parameter σ_0 may exceed the bound given by the right-hand side (3.30) (if $1 + \beta \geq p$) or (3.32) (if $1 + \beta < p$), and also that these bounds may just fail by a small margin at an unsuccessful iteration, resulting in an increase of σ_k by a factor γ_3 before the relevant bound applies. $\qquad\square$

Having now derived an iteration independent upper bound on σ_k, we may return to the model decrease given by Lemma 3.5.

Lemma 3.8 Suppose that AS.1– AS.5 hold and that $\epsilon_* < 1$. Then, as long as the algorithm does not terminate,

- if $1 + \beta \geq p$, then

$$f(x_k) - m(x_k + s_k) \geq \kappa_1^m \epsilon_*^{\frac{p}{p-1}}. \tag{3.34}$$

  where

$$\kappa_1^m \stackrel{\text{def}}{=} \frac{1}{4} \min \left[\frac{1}{2\kappa_B}, \left(\frac{p}{2\kappa_1^\sigma} \right)^{\frac{1}{p-1}} \right], \tag{3.35}$$

- if $1 + \beta < p$, then

$$f(x_k) - m(x_k + s_k) \geq \kappa_2^m \epsilon_*^{1+\frac{1}{\beta}}. \tag{3.36}$$

  where

$$\kappa_2^m \stackrel{\text{def}}{=} \frac{1}{4} \min \left[\frac{1}{2\kappa_B}, \left(\frac{p}{2\kappa_2^\sigma} \right)^{\frac{1}{p-1}} \right]. \tag{3.37}$$

Proof. Assume first that $1 + \beta \geq p$. As above, this implies that $p \in [1, 2]$ and hence, because of (2.7), that $g_k^T B_k g_k \geq 0$. Taking into account that, in this case,

$$g_k^T B_k g_k \leq \kappa_B \|g_k\|^2$$

because of AS.5, substituting (3.26) into (3.14) and using (3.26) and the fact that $\|g_k\| \geq \epsilon_*$ as long as the algorithm has not terminated, yields that

$$
\begin{aligned}
f(x_k) - m_k(x_k + s_k) &\geq \tfrac{1}{4} \min \left[\frac{\epsilon_*^2}{2\kappa_B}, \left(\frac{p}{2\kappa_1^\sigma} \right)^{\frac{1}{p-1}} \epsilon_*^{\frac{p}{p-1}} \right] \\
&\geq \tfrac{1}{4} \min \left[\frac{1}{2\kappa_B}, \left(\frac{p}{2\kappa_1^\sigma} \right)^{\frac{1}{p-1}} \right] \min \left(\epsilon_*^2, \epsilon_*^{\frac{p}{p-1}} \right)
\end{aligned}
$$

and (3.34) follows since $\epsilon_* < 1$ and

$$
\frac{p}{p-1} \geq 2 \ \text{ for } \ p \in [1, 2].
$$

Consider now the case where $1 + \beta < p$. Substituting now (3.28) into (3.14), using (3.28), AS.5 and the fact that $\|g_k\| \geq \epsilon_*$ as long as the algorithm has not terminated, we obtain that

$$
\begin{aligned}
f(x_k) - m_k(x_k + s_k) &\geq \tfrac{1}{4} \min \left[\underbrace{\frac{\epsilon_*^2}{2\kappa_B}}_{g_k^T B_k g_k > 0}, \left(\frac{p\, \epsilon_*^p}{2 \max \left[\kappa_2^\sigma, \kappa_3^\sigma \epsilon_*^{\frac{1+\beta-p}{\beta}} \right]} \right)^{\frac{1}{p-1}} \right] \\
&\geq \tfrac{1}{4} \min \left[\frac{1}{2\kappa_B}, \left(\frac{p}{2 \max \left[\kappa_2^\sigma, \kappa_3^\sigma \right]} \right)^{\frac{1}{p-1}} \right] \min \left(\epsilon_*^2, \epsilon_*^{\frac{p}{p-1}}, \epsilon_*^{1+\frac{1}{\beta}} \right).
\end{aligned}
$$

which yields (3.36) since $\epsilon_* < 1$ and, for $1 + \beta < p$ and $\beta \in (0, 1]$,

$$
1 + \frac{1}{\beta} \geq \frac{p}{p-1} \quad \text{and} \quad 1 + \frac{1}{\beta} \geq 2.
$$

$\square$

We now recall an important technical lemma which, in effect, gives a bound on the total number of unsuccessful iterations before iteration k as a function of the number of successful ones.

Lemma 3.9 The mechanism of Algorithm 2.1 guarantees that, if

$$
\sigma_k \leq \sigma_{\max}, \tag{3.38}
$$

for some $\sigma_{\max} > 0$, then

$$
k \leq |\mathcal{S}_k| \left(1 + \frac{|\log \gamma_1|}{\log \gamma_2} \right) + \frac{1}{\log \gamma_2} \log \left(\frac{\sigma_{\max}}{\sigma_0} \right). \tag{3.39}
$$

Proof. See [5]. $\square$

We are now ready to prove our main result on the worst-case complexity of Algorithm 2.1.

Theorem 3.10 Suppose that AS.1–AS.5 hold and that ϵ_* defined in (3.1) satisfies $\epsilon_* < 1$.

1. If $1 + \beta \geq p$, there exist constants κ_p^s, κ_p^a and κ_p^c such that, for any $\epsilon > 0$, Algorithm 2.1 requires at most

$$\left\lfloor \kappa_p^s \, \frac{f(x_0) - f_*}{\epsilon_*^{\frac{p}{p-1}}} \right\rfloor \tag{3.40}$$

successful iterations (and gradient evaluations), and a total of

$$\left\lfloor \kappa_p^a \, \frac{f(x_0) - f_*}{\epsilon_*^{\frac{p}{p-1}}} + \kappa_p^c \right\rfloor \tag{3.41}$$

iterations (and objective function evaluations) before producing an iterate x_ϵ such that $\|g(x_\epsilon)\| \leq \epsilon_*$ or $f(x_\epsilon) \leq f_{\text{target}}$.

2. If $1 + \beta < p$, there exist constants κ_β^s, κ_β^a, κ_β^b and κ_β^c such that, for all $\epsilon > 0$, Algorithm 2.1 requires at most

$$\left\lfloor \kappa_\beta^s \, \frac{f(x_0) - f_*}{\epsilon_*^{1 + \frac{1}{\beta}}} \right\rfloor \tag{3.42}$$

successful iterations (and gradient evaluations) and a total of

$$\left\lfloor \kappa_\beta^a \, \frac{f(x_0) - f_*}{\epsilon_*^{1 + \frac{1}{\beta}}} + \kappa_\beta^b \, |\log \epsilon_*| + \kappa_\beta^c \right\rfloor \tag{3.43}$$

iterations (and objective function evaluations) before producing an iterate x_ϵ such that $\|g(x_\epsilon)\| \leq \epsilon_*$ or $f(x_\epsilon) \leq f_{\text{target}}$.

In the above statements the constants are given by

$$\kappa_p^s = \kappa_\beta^s \overset{\text{def}}{=} \frac{1}{\eta_1 \kappa_m}, \tag{3.44}$$

$$\kappa_p^a \overset{\text{def}}{=} \frac{1}{\eta_1 \kappa_m} \left(1 + \frac{|\log \gamma_1|}{\log \gamma_2} \right), \quad \kappa_p^c \overset{\text{def}}{=} \frac{1}{\log \gamma_2} \log \left(\frac{\kappa_1^\sigma}{\sigma_0} \right), \tag{3.45}$$

$$\kappa_\beta^a \overset{\text{def}}{=} \frac{1}{\eta_1 \kappa_m} \left(1 + \frac{|\log \gamma_1|}{\log \gamma_2} \right), \quad \kappa_\beta^b \overset{\text{def}}{=} \frac{p - \beta - 1}{\beta \log \gamma_2} \tag{3.46}$$

and

$$\kappa_\beta^c \overset{\text{def}}{=} \frac{1}{\log \gamma_2} \Big(\log \left(\max[1, \kappa_2^\sigma, \kappa_3^\sigma] \right) + |\log(\sigma_0)| \Big), \tag{3.47}$$

where

$$\kappa_1 \overset{\text{def}}{=} 2p \left(\frac{L_\beta}{1+\beta} \right)^{\frac{p-1}{\beta}}, \quad \kappa_2 \overset{\text{def}}{=} \max \left[2p \left(2\,\kappa_B \right)^{p-1}, 2^{\frac{2+\beta}{\beta}} p\,\kappa_3^{\frac{1}{\beta}}, 8\,p\,\kappa_3 \right] \tag{3.48}$$

with

$$\kappa_3 \overset{\text{def}}{=} \left(\left[\frac{L_\beta}{1+\beta} + \tfrac{1}{2}\kappa_B \right] \left[\frac{4}{1-\eta_2} \right] \right)^{p-1}, \tag{3.49}$$

$$\kappa_1^\sigma \overset{\text{def}}{=} \gamma_3 \kappa_1 \kappa_{gu}^{1+\beta-p}, \quad \kappa_2^\sigma \overset{\text{def}}{=} \gamma_3 \max \left[0, \underbrace{\kappa_2 \kappa_{gu}^{2-p}}_{p \le 2} \right], \quad \kappa_2^\sigma \overset{\text{def}}{=} \max \gamma_3 \kappa_2. \tag{3.50}$$

and

$$\kappa_1^m \overset{\text{def}}{=} \frac{1}{4} \min \left[\frac{1}{2\kappa_B}, \left(\frac{p}{2\kappa_1^\sigma} \right)^{\frac{1}{p-1}} \right] \quad \text{and} \quad \kappa_2^m \overset{\text{def}}{=} \frac{1}{4} \min \left[\frac{1}{2\kappa_B}, \left(\frac{p}{2\kappa_2^\sigma} \right)^{\frac{1}{p-1}} \right] \tag{3.51}$$

Proof. Consider first the case where $1 + \beta \ge p$. We then deduce from AS.3, the definition of a successful iteration and (3.34) in Lemma 3.8, that, as long as the algorithm has not terminated,

$$\begin{aligned}
f(x_0) - f_* &\ge f(x_0) - f(x_{k+1}) \\
&= \sum_{j \in \mathcal{S}_k} \left[f(x_j) - f(x_j + s_j) \right] \\
&\ge \eta_1 \sum_{j \in \mathcal{S}_k} \left[f(x_j) - m_j(x_j + s_j) \right] \\
&> \eta_1 \, \kappa_m \, \epsilon_*^{\frac{p}{p-1}} \, |\mathcal{S}_k|,
\end{aligned} \tag{3.52}$$

where $|\mathcal{S}_k|$ is the cardinality of $\mathcal{S}_k \overset{\text{def}}{=} \{ j \in \mathcal{S} \mid j \le k \}$, that is the number of successful iterations up to iteration k. This provides an upper bound on $|\mathcal{S}_k|$ which is independent of k and ϵ_*, from which we obtain the bound (3.40) with (3.44). Calling now upon Lemma 3.9 and (3.26), we deduce that the total number of iterations (and function evaluations) cannot exceed

$$\kappa_p^s \frac{f(x_0) - f_*}{\epsilon_*^{\frac{p}{p-1}}} \left(1 + \frac{|\log \gamma_1|}{\log \gamma_2} \right) + \frac{1}{\log \gamma_2} \log \left(\frac{\kappa_1^\sigma}{\sigma_0} \right),$$

which then gives the bound (3.41) with (3.45).

The proof for the case where $1 + \beta < p$ is derived in a manner entirely similar to that used for the case where $1 + \beta \ge p$, replacing $\epsilon^{\frac{p}{p-1}}$ by $\epsilon^{1+\frac{1}{\beta}}$ in (3.52) since (3.34) is used instead of (3.36), and also noting that, when using (3.28) instead of (3.26) in Lemma 3.9,

$$\log \left(\frac{\max \left[\kappa_2^\sigma, \kappa_3^\sigma \epsilon_*^{\frac{1+\beta-p}{\beta}} \right]}{\sigma_0} \right) \le \left| \frac{1+\beta-p}{\beta} \right| |\log \epsilon_*| + \log(\max[1, \kappa_2^\sigma, \kappa_3^\sigma]) + |\log(\sigma_0)|.$$

We may thus deduce that (3.42) and (3.43) hold with (3.46)–(3.51). □

A close look at the expressions of the constants in (3.44)-(3.51) reveals that the global upper bound on the gradient norm, κ_{gu}, only occurs in the case where $p < 2$. Therefore, AS.4 is only needed in this case since the existence of $\kappa_{gl} \geq 0$ is always ensured by the non-negativity of $\|g(x)\|$.

4 Sharpness

We now show that the bound specified by part (ii) of Theorem 3.10 is essentially sharp in the sense that we exhibit a class of one-dimensional examples where the number of iterations necessary to produce an approximate first-order critical point is arbitrarily close to the theorem's bound[1]. To achieve this goal, we first establish sequences of iterates $\{x_k\}$, function values $\{f(x_k)\}$, gradient values $\{g_k\}$ and regularization parameter values $\{\sigma_k\}$ which can be generated by Algorithm 2.1 and such that the gradient values converge to zero sufficiently slowly to attain the desired lower bound on the number of iterations (and evaluations). Once these are defined, we construct a function $f(x)$ which interpolates these function and gradient values and finally prove that all our assumptions are satisfied. Because the derivation of the complexity bound involves an increasing sequence of regularization parameters $\{\sigma_k\}$, our example is unfortunately somewhat complicated because it has to include both successful and unsuccessful iterations. We choose to construct it such that all even iterations are unsuccessful and all odd ones are successful.

Consider the gradient sequence defined, for $p > 1 + \beta$, any arbitrarily small $\tau \in (0,1)$, a positive integer q and all $k \geq 0$, by

$$g_{2k} = -\left(\frac{1}{k+q}\right)^{\frac{\beta}{1+\beta}+\tau}, \qquad g_{2k+1} = g_{2k}. \tag{4.1}$$

and observe that the sequence of gradient norms $\{\|g_k\|\}$ is non-increasing for any choice of q. Assume first that $q = 1$. This definition implies that

$$\frac{|g_{2k+3}|}{|g_{2k+1}|} \to 1 \tag{4.2}$$

when k tends to infinity, and thus that

$$\omega_{2k-1} \stackrel{\text{def}}{=} \left(\frac{|g_{2k+1}|^{\frac{1}{\beta}}}{|g_{2k+1}|^{\frac{1}{\beta}} + \frac{1}{2}|g_{2k+3}|^{\frac{1}{\beta}}}\right)^{p-1} \left(\frac{|g_{2k}|^{\frac{1}{\beta}}}{|g_{2k-1}|^{\frac{1}{\beta}}}\right)^{1+\beta-p} \to \left(\frac{2}{3}\right)^{p-1}. \tag{4.3}$$

Hence, there exists an integer $\ell \geq 2$ such that

$$\omega_{2k-1} \in \left[\frac{1}{2}\left(\frac{2}{3}\right)^{p-1}, \left(\frac{5}{6}\right)^{p-1}\right] \subset (0,1) \quad \text{for} \quad k \geq \ell. \tag{4.4}$$

We now (re)define q in (4.1) by setting $q = \ell$, in effect shifting the $\{k\}$ sequence by ℓ such that (4.2)-(4.4) holds with (4.1) for the complete shifted sequence. Note that q only depends

---

[1]Whether this can also be achieved for part (i) of the theorem is still unknown at this point.

on β and τ and is independent of ϵ. Observe also that the rate of (monotonic) convergence of the sequence $\{g_k\}$ to zero ensures that, for any $\epsilon \in (0,1)$, $|g_k| \leq \epsilon$ only for k larger than $2(\lfloor \epsilon^{-\frac{1+\beta}{\beta+\tau(1+\beta)}} \rfloor - q)$.

In order to ensure the proper rate of increase of σ_k, we choose to set

$$\sigma_{2k+1} = |g_{2k+1}|^{\frac{1+\beta-p}{\beta}} \tag{4.5}$$

for all $k \geq 0$ (remembering that odd iterations are successful), while the value of σ_{2k} is still to be determined within the constraints of (2.11). Associated with the sequence $\{g_k\}$, we define the sequence of iterates $\{x_k\}$ by

$$x_0 = x_1 = 0, \quad x_{2k+2} = x_{2k+1} + s_{2k+1} = x_{2k+3} \quad (k \geq 0).$$

In this definition, the step s_{2k+1} at a successful iterations is computed by minimizing the model (2.4) with $B_{2k+1} = 0$, that is

$$m_{2k+1}(x_{2k+1} + s) = f(x_{2k+1}) + g_{2k+1} s + \frac{\sigma_{2k+1}}{p}|s|^p,$$

over s, where the function value $f(x_{2k+1})$ is still to be defined. A simple calculation shows that

$$s_{2k+1} = \left(\frac{|g_{2k+1}|}{\sigma_{2k+1}}\right)^{\frac{1}{p-1}} = |g_{2k+1}|^{\frac{1}{\beta}} \leq |g_0|^{\frac{1}{\beta}} < 1, \tag{4.6}$$

where we substituted (4.5) to obtain the last equality, and that

$$\Delta m_{2k+1} \stackrel{\text{def}}{=} m_{2k+1}(x_{2k+1}) - m_{2k+1}(x_{2k+1} + s_{2k+1})$$

$$= \left(1 - \tfrac{1}{p}\right)|g_{2k+1}|^{\frac{1+\beta}{\beta}} \tag{4.7}$$

$$= \left(1 - \tfrac{1}{p}\right)|g_{2k+1}s_{2k+1}|.$$

Similarly, we also define the step s_{2k} as the minimizer of $m_{2k}(x_{2k} + s)$ with $B_{2k} = 0$, yielding

$$s_{2k} = \left(\frac{|g_{2k}|}{\sigma_{2k}}\right)^{\frac{1}{p-1}} \tag{4.8}$$

and

$$\Delta m_{2k} \stackrel{\text{def}}{=} m_{2k}(x_{2k}) - m_{2k}(x_{2k} + s_{2k}) = \left(1 - \frac{1}{p}\right)\left(\frac{|g_{2k}|^p}{\sigma_{2k}}\right)^{\frac{1}{p-1}} = \left(1 - \frac{1}{p}\right)|g_{2k}s_{2k}|. \tag{4.9}$$

The sequence of function values is then defined by

$$f(x_0) = f(x_1) = 0, \quad f(x_{2k+2}) = m_{2k+1}(x_{2k+1} + s_{2k+1}) = f(x_{2k+3}) \quad (k \geq 0), \tag{4.10}$$

where the second part guarantees the very successful nature of iteration $2k + 1$. We observe that, for $k \geq 0$,

$$f(x_{2k}) - f(x_{2k+1}) = 0$$

since iteration $2k$ is unsuccessful, and

$$f(x_{2k+1}) - f(x_{2k+2}) = \Delta m_{2k+1} = \left(1 - \frac{1}{p}\right)|g_{2k+1}|^{\frac{1+\beta}{\beta}}, \tag{4.11}$$

yielding that, for every $k \geq 0$, that

$$\begin{aligned}
f(x_0) - f(x_{2k+2}) &= \sum_{j=0}^{k}[f(x_{2j+1}) - f(x_{2j+2})] \\
&= \left(1 - \frac{1}{p}\right)\sum_{j=0}^{k}|g_{2j+1}|^{\frac{1+\beta}{\beta}} \\
&= \left(1 - \frac{1}{p}\right)\sum_{j=0}^{k}\left(\frac{1}{j+q}\right)^{1+\frac{1+\beta}{\beta}\tau}.
\end{aligned}$$

Hence the sequence $\{f(x_k)\}$ is bounded below by

$$f_\infty \overset{\text{def}}{=} \left(1 - \frac{1}{p}\right)\left[-\zeta\left(1 + \frac{1+\beta}{\beta}\tau\right) + \sum_{j=1}^{q-1}\left(\frac{1}{j}\right)^{1+\frac{1+\beta}{\beta}\tau}\right] > -\infty, \tag{4.12}$$

where $\zeta(\cdot)$ is the Riemann zeta function. We conclude the definition of the sequences involved in our example by selecting σ_{2k} in order to impose that, for all $k \geq 0$,

$$s_{2k} = s_{2k+1} + \tfrac{1}{2}s_{2k+3} \tag{4.13}$$

where $\frac{1}{2} \in [\frac{1}{2}, 1)$ is chosen as when defining q above. Using (4.8), this is equivalent to asking that

$$\frac{|g_{2k}|}{\sigma_{2k}} = (s_{2k+1} + \tfrac{1}{2}s_{2k+3})^{p-1},$$

which, in view of (4.5), is equivalent to requiring that

$$\frac{\sigma_{2k}}{\sigma_{2k-1}} = \frac{|g_{2k}|}{|g_{2k-1}|^{\frac{1+\beta-p}{\beta}}}\left(\frac{1}{s_{2k+1} + \tfrac{1}{2}s_{2k+3}}\right)^{p-1}.$$

If we now take (4.6), (4.3) and (4.4) into account, this amounts to imposing that

$$\frac{\sigma_{2k}}{\sigma_{2k-1}} = \omega_{2k-1} \in \left[\frac{1}{2}\left(\frac{2}{3}\right)^{p-1}, \left(\frac{5}{6}\right)^{p-1}\right],$$

therefore satisfying (2.11) at successful iterations for a choice of $\gamma_1 \leq \frac{1}{2}\left(\frac{2}{3}\right)^{p-1}$. (In order to start the recursion, we (arbitrarily) define σ_{-1} by (4.5) with $k = -1$ and $g_{-1} = -[1/(q - 1)]^{\frac{\beta}{1+\beta}+\tau}$.) We also observe that, for large enough k,

$$\frac{\sigma_{2k+1}}{\sigma_{2k}} = \frac{|g_{2k+1}|^{\frac{1+\beta-p}{\beta}}}{\omega_{2k-1}\sigma_{2k-1}} = \left(\frac{s_{2k+1} + \tfrac{1}{2}s_{2k+3}}{s_{2k+1}}\right)^{p-1} \in \left[\left(\frac{s_1 + \tfrac{1}{2}s_3}{s_1}\right)^{p-1}, \left(\frac{3}{2}\right)^{p-1}\right] \tag{4.14}$$

and (2.11) therefore also holds at unsuccessful iterations. As a consequence of this somewhat lengthy description, we may therefore deduce that the sequences $\{x_k\}$, $\{g_k\}$ $\{\sigma_k\}$ and $\{f(x_k)\}$

may be generated by Algorithm 2.1 provided only that iteration $2k$ is indeed unsuccessful, that is if

$$f(x_{2k}) - f(x_{2k} + s_{2k}) < \eta_1 \Delta m_{2k},$$

where $f(x_{2k} + s_{2k})$ is the still undefined value of our putative objective function at $x_{2k} + s_{2k} = x_{2k+3} + \frac{1}{2}s_{2k+3}$. This condition is obviously satisfied if we also impose that $f(x_{2k+3} + \frac{1}{2}s_{2k+3}) = f^{2k}_{2k+3}$, where

$$f^{2k}_{2k+3} \stackrel{\text{def}}{=} \max[\, f(x_{2k+3}),\ f(x_{2k}) - 0.99\,\eta_1 \Delta m_{2k},\ f(x_{2k+4}) - \tfrac{1}{2}g_{2k+4}s_{2k+3}\,]. \tag{4.15}$$

Note that this last condition ensures that

$$f(x_{2k+2}) = f(x_{2k+3}) \le f^{2k}_{2k+3}. \tag{4.16}$$

and also, since $f(x_{2k}) = f(x_{2k+1}) > f(x_{2k+3})$, that

$$f^{2k}_{2k+3} \ge f(x_{2k+4}) - \tfrac{1}{2}g_{2k+4}s_{2k+3} \quad \Rightarrow \quad f^{2k}_{2k+3} \in [f(x_{2k+3}), f(x_{2k+1})]. \tag{4.17}$$

We now turn to the definition of the objective function $f(x)$ which must interpolate function and gradient values at the iterates. We start by noting that, for arbitrary $a > 0$ and $s > 0$, function values f_a and f_b and gradient values g_a and g_b, it is possible to construct a function

$$f_{as}(t) = f_a + g_a t + c_{as}\, [\sin(\phi_{as} t)]^{1+\beta} \tag{4.18}$$

on the interval $[a, a + s]$ where the parameters c_{as} and $\phi_{as} \in (0, \pi]$ can be determined to ensure that

$$f_{as}(0) = f_a, \quad g_{as}(0) = g_a, \quad f_a(s) = f_b \text{ and } g_{as}(s) = g_b.$$

Indeed, since

$$g_{as}(t) = g_a + c_{as}(1 + \beta)\phi_{as}\, [\sin(\phi_{as} t)]^{\beta} \cos(\phi_{as} t), \tag{4.19}$$

we deduce that

$$g_b - g_a = c_{as}(1 + \beta)\phi_{as}\, [\sin(\phi_{as} s)]^{\beta} \cos(\phi_{as} s), \tag{4.20}$$

which may substitute in (4.18) to obtain that

$$f_b - f_a = g_a s + \frac{(g_b - g_a) \sin(\phi_{as} s)}{(1 + \beta)\phi_{as} \cos(\phi_{as} s)},$$

and hence conclude that $\phi_{as}s$ is the smallest positive root θ_{as} of the nonlinear equation

$$\frac{\sin(\theta)}{\theta} = \nu_{as} \cos(\theta), \quad \text{where} \quad \nu_{as} = (1 + \beta)\frac{f_b - f_a - g_a s}{(g_b - g_a)s}. \tag{4.21}$$

It is easy to check that such a root always exist in $(0, \frac{\pi}{2}]$ if $\nu_{as} > 1$. Given ϕ_{as}, or, equivalently, $\theta_{as} = \phi_{as}s$, we also obtain that

$$c_{as} = \frac{f_b - f_a - g_a s}{[\sin(\theta_{as})]^{1+\beta}}.$$

We now use this interpolation technique on each of the sequence of intervals specified in Table 4.2. Observe that the function is interpolated for every successful step in two pieces with an intermediate point corresponding (for all iterations beyond the first) to the penultimate

unsuccessful trial point, where condition (4.15) is imposed as well as a zero gradient. We also choose (arbitrarily)

$$f_1^{-2} = |g_{-1}|^{(1+\beta)/\beta} - 0.99 \frac{3\eta_1}{2} \left(\frac{|g_{-1}|^p}{\sigma_{-1}} \right)^{1/(p-1)}$$

(corresponding to a fictitious unsuccessful iteration of index $k = -2$ with $g_{-2} = g_{-1}$ and $\sigma_{-2} = \sigma_{-1}/(1 + \frac{1}{2})^{p-1}$).

Iteration	Interpolation interval	Interpolated values			
k	$[a, a+s]$	f_a	g_a	f_b	g_b
1	$[x_1, x_1 + \frac{1}{2}s_1]$	$f(x_0) = f(x_1)$	g_1	f_1^{-2}	0
1	$[x_1 + \frac{1}{2}s_1, x_2]$	0	0	$f(x_2)$	g_2
3	$[x_3, x_3 + \frac{1}{2}s_3]$	$f(x_2) = f(x_3)$	g_3	f_3^0	0
3	$[x_3 + \frac{1}{2}s_3, x_4]$	f_3^0	0	$f(x_4)$	g_4
5	$[x_5, x_5 + \frac{1}{2}s_5]$	$f(x_4) = f(x_5)$	g_5	f_5^2	0
5	$[x_5 + \frac{1}{2}s_5, x_6]$	f_5^2	0	$f(x_6)$	g_6
$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$
$2k+1$	$[x_{2k+1}, x_{2k+1} + \frac{1}{2}s_{2k+1}]$	$f(x_{2k}) = f(x_{2k+1})$	g_{2k+1}	f_{2k+1}^{2k-2}	0
$2k+1$	$[x_{2k+1} + \frac{1}{2}s_{2k+1}, x_{2k+2}]$	f_{2k+1}^{2k-2}	0	$f(x_{2k+2})$	g_{2k+2}
$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$

Table 4.2: Interpolation conditions for successful iterations

For the function (4.18) and its gradient (4.19) to be well-defined, we still need that $\nu_{as} > 1$ for each interpolation interval. Consider the first such interval at iteration $2k+1$ ($k \geq 0$) and ν_{2k+1}^1, the value of ν_{as} corresponding to that interval. Using (4.16), we obtain that

$$\nu_{2k+1}^1 = (1+\beta) \frac{f_{2k+1}^{2k-1} - f(x_{2k+1}) + \frac{1}{2}|g_{2k+1}s_{2k+1}|}{\frac{1}{2}|g_{2k+1}s_{2k+1}|} \geq 1 + \beta > 1 \tag{4.22}$$

as desired. For the second interpolation interval at iteration $2k+1$, we have that

$$\nu_{2k+1}^2 = (1+\beta) \frac{f_{2k+1}^{2k-2} - f(x_{2k+2})}{(1 - \frac{1}{2})|g_{2k+2}s_{2k+1}|} \geq (1+\beta) \frac{\frac{1}{2}|g_{2k+2}s_{2k+1}|}{\frac{1}{2}|g_{2k+2}s_{2k+1}|} = 1 + \beta > 1 \tag{4.23}$$

where we have used (4.15) to derive the inequality. We therefore obtain from (4.22) and (4.23) that, for all $k \geq 0$, the desired roots θ_{2k+1}^1 and θ_{2k+1}^2 exist and satisfy

$$\theta_{2k+1}^1 \leq \frac{\pi}{2} \quad \text{and} \quad \theta_{2k+1}^2 \leq \frac{\pi}{2}. \tag{4.24}$$

As a consequence $\sin(\phi_{2k+1}^i t)$ is positive on each interpolation interval ($i = 1, 2$), and our interpolating function and its gradient are also well-defined for each interval. Moreover, since both ν_{2k+1}^1 and ν_{2k+1}^2 are bounded below by $1 + \beta$, we obtain that there is a constant $\kappa_\theta > 0$ such that

$$\theta_{2k+1}^1 \in [\kappa_\theta, \frac{\pi}{2}] \quad \text{and} \quad \theta_{2k+1}^2 \in [\kappa_\theta, \frac{\pi}{2}], \tag{4.25}$$

and thus that there exists a constant $\kappa_{\sin} > 0$ independent of k such that

$$\sin(\theta^1_{2k+1}) \geq \kappa_{\sin} \quad \text{and} \quad \sin(\theta^2_{2k+1}) \geq \kappa_{\sin}. \tag{4.26}$$

Figure 4.1 shows the shape of the resulting function and Figure 4.2 the shape of its gradient, whose construction implies that AS.1 holds. Figure 4.1 also shows the shape of the models $m_{2k}(x_{2k} + s)$ on the intervals $[x_{2k}, x_{2k} + s_{2k}] = [x_{2k}, x_{2k+3} + \frac{1}{2}s_{2k+3}]$ (dashed lines), illustrating that the model is a bad predictor of the objective function value at the point $x_{2k} + s_{2k}$, causing the unsuccessful nature of iteration $2k$. Note that $f(x)$ may be extended smoothly into a decreasing function for $x < 0$.

Figure 4.1: The shape of $f(x)$ for the first 8 successful iterations and the shape of the model at each unsuccessful iteration (dashed) for $\beta = 0.45$, $p = 2.1$, $\tau = 0.001$, $\eta_1 = 0.6$ and $q = 3$

As can be checked in these figures, $f(x)$ is nonconvex and continuously differentiable. The form (4.19) implies that $g(x)$ varies very quickly at the beginning of each interpolation interval, which is visible in Figure 4.2.

We now investigate the properties of our interpolant further, and observe that, because of (4.11), (4.17), (4.7), the fact that $f(x_{2k}) = f(x_{2k+1})$ and the inequality $|g_{2k+2}s_{2k+1}| \leq |g_{2k-1}s_{2k-1}|$,

$$
\begin{aligned}
f^{2k-2}_{2k+1} - f(x_{2k+1}) \;\; &\leq \;\; \max[f(x_{2k-1}) - f(x_{2k+1}),\, f(x_{2k+2}) - \tfrac{1}{2}g_{2k+2}s_{2k+1} - f(x_{2k+1})] \\
&< \;\; \max[\Delta m_{2k-1},\, \tfrac{1}{2}|g_{2k+2}s_{2k+1}|] \\
&< \;\; \max[\,|g_{2k-1}s_{2k-1}|,\, |g_{2k+2}s_{2k+1}|\,] \\
x \qquad\qquad\quad &< \;\; |g_{2k-1}s_{2k-1}|
\end{aligned}
$$

Figure 4.2: The shape of $g(x)$ for the first 8 successful iterations for $\beta = 0.45$, $p = 2.1$, $\tau = 0.001$, $\eta_1 = 0.6$ and $q = 3$

and hence that

$$
\begin{aligned}
\nu_{2k+1}^1 \;&=\; (1+\beta)\,\frac{f_{2k+1}^{2k-2} - f(x_{2k+1}) + \frac{1}{2}|g_{2k+1}s_{2k+1}|}{\frac{1}{2}|g_{2k+1}s_{2k+1}|} \\[2mm]
&\leq\; \frac{2(1+\beta)}{|g_{2k+1}s_{2k+1}|}\left(|g_{2k-1}s_{2k-1}| + \tfrac{1}{2}|g_{2k+1}s_{2k+1}|\right) \\[2mm]
&<\; \frac{2(1+\beta)}{|g_{2k+1}s_{2k+1}|}\left(2|g_{2k-1}s_{2k-1}|\right) \\[2mm]
&=\; 4(1+\beta)\left|\frac{g_{2k-1}}{g_{2k+1}}\right|^{\frac{1+\beta}{\beta}} \\[2mm]
&\to\; 4(1+\beta)
\end{aligned}
\tag{4.27}
$$

where we used (4.2). Similarly, using (4.17), (4.10), (4.7), (4.11) and (4.1) in succession, we

obtain that

$$
\begin{aligned}
\nu_{2k+1}^2 &= (1+\beta)\frac{f_{2k+1}^{2k-2} - f(x_{2k+2})}{\frac{1}{2}|g_{2k+2}s_{2k+1}|} \\
&\leq \frac{2(1+\beta)\max[\,f(x_{2k-1}) - f(x_{2k+2}),\, \frac{1}{2}|g_{2k+2}s_{2k+1}|\,]}{|g_{2k+2}s_{2k+1}|} \\
&\leq \frac{2(1+\beta)\max[\,\Delta m_{2k-1} + \Delta m_{2k+1},\, \frac{1}{2}|g_{2k+2}s_{2k+1}|\,]}{|g_{2k+2}s_{2k+1}|} \\
&\leq 2(1+\beta)\max\left[\frac{2\Delta m_{2k-1}}{|g_{2k+2}s_{2k+1}|},\, \frac{1}{2}\right] \\
&= 2(1+\beta)\max\left[2\left(1-\frac{1}{p}\right)\frac{\Delta m_{2k-1}}{\Delta m_{2k+1}}\frac{|g_{2k+1}s_{2k+1}|}{|g_{2k+2}s_{2k+1}|},\, \frac{1}{2}\right] \\
&= 2(1+\beta)\max\left[2\left(1-\frac{1}{p}\right)\left|\frac{g_{2k-1}}{g_{2k+1}}\right|^{\frac{1+\beta}{\beta}}\frac{|g_{2k+1}s_{2k+1}|}{|g_{2k+2}s_{2k+1}|},\, \frac{1}{2}\right] \\
&= 2(1+\beta)\max\left[2\left(1-\frac{1}{p}\right)\left|\frac{g_{2k-1}}{g_{2k+1}}\right|^{\frac{1+\beta}{\beta}}\frac{|g_{2k+1}|}{|g_{2k+2}|},\, \frac{1}{2}\right] \\
&\to 2(1+\beta)\max\left[2\left(1-\frac{1}{p}\right),\, \frac{1}{2}\right].
\end{aligned}
\tag{4.28}
$$

We may therefore deduce from (4.27) and (4.28) that there exists a constant $\kappa_\nu > 0$ independent of k such that, for all $k \geq 0$,

$$\nu_{2k+1}^1 \leq \kappa_\nu \ \text{ and } \ \nu_{2k+1}^2 \leq \kappa_\nu.$$

As a consequence, and since the nonlinear equation in (4.21) can be written in the form

$$\tan(\theta) = \nu_{as}\theta,$$

we obtain that θ_{as} is uniformly bounded away from $\frac{\pi}{2}$ and hence that there exists a constant $\kappa_{\cos} > 0$ such that

$$\cos(\theta_{as}) = \cos(\phi_{as}s) \geq \kappa_{\cos} \tag{4.29}$$

for every interpolation interval.

Consider now $0 \leq t_1 < t_2 \leq s$ for a given interpolation interval $[a, a+s]$. Because of (4.24), we then have that

$$
\begin{aligned}
|g(t_2) - g(t_1)| &= |c_{as}|(1+\beta)\phi_{as}\left\{\left|[\sin(\phi_{as}t_2)]^\beta\cos(\phi_{as}t_2) - [\sin(\phi_{as}t_1)]^\beta\cos(\phi_{as}t_1)\right|\right\} \\
&\leq |c_{as}|(1+\beta)\phi_{as}\left\{\left|[\sin(\phi_{as}t_2)]^\beta\cos(\phi_{as}t_2) - [\sin(\phi_{as}t_2)]^\beta\cos(\phi_{as}t_1)\right|\right. \\
&\qquad\qquad\qquad\qquad \left. + \left|[\sin(\phi_{as}t_2)]^\beta\cos(\phi_{as}t_1) - [\sin(\phi_{as}t_1)]^\beta\cos(\phi_{as}t_1)\right|\right\} \\
&= |c_{as}|(1+\beta)\phi_{as}\left\{\left|[\sin(\phi_{as}t_2)]^\beta\right|\,|\cos(\phi_{as}t_2) - \cos(\phi_{as}t_1)|\right. \\
&\qquad\qquad\qquad\qquad \left. + |\cos(\phi_{as}t_1)|\,\left|[\sin(\phi_{as}t_2)]^\beta - [\sin(\phi_{as}t_1)]^\beta\right|\right\} \\
&\leq |c_{as}|(1+\beta)\phi_{as}\left\{|\cos(\phi_{as}t_2) - \cos(\phi_{as}t_1)| + \left|[\sin(\phi_{as}t_2)]^\beta - [\sin(\phi_{as}t_1)]^\beta\right|\right\}
\end{aligned}
$$

Now, using the mean-value theorem,

$$|\cos(\phi_{as}t_2) - \cos(\phi_{as}t_1)| = |\sin(\xi)|\,\phi_{as}|t_2 - t_1| \leq \left(\frac{\pi}{2}\right)^{1-\beta}\phi_{as}^\beta|t_2 - t_1|^\beta \tag{4.30}$$

where $\xi \in (\phi_{as} t_1, \phi_{as} t_2)$ and where we have used the fact

$$\phi_{as}|t_2 - t_1| = \frac{\pi}{2}\left(\frac{2\phi_{as}|t_2 - t_1|}{\pi}\right) \le \frac{\pi}{2}\left(\frac{2\phi_{as}|t_2 - t_1|}{\pi}\right)^\beta.$$

because $\phi_{as}|t_2 - t_1| \le \phi_{as}s \le \frac{\pi}{2}$. Moreover, using the inequality

$$|u^\beta - v^\beta| \le |u - v|^\beta \quad \text{for all} \quad u, v \in [0, 1], \tag{4.31}$$

and the fact that

$$\sin\left(\frac{\phi_{as}}{2}(t_2 - t_1)\right) < \frac{\phi_{as}}{2}(t_2 - t_1)$$

since $\phi_{as}(t_2 - t_1) \le \phi_{as}s \le \frac{\pi}{2}$, we deduce that

$$
\begin{aligned}
\left|[\sin(\phi_{as}t_2)]^\beta - [\sin(\phi_{as}t_1)]^\beta\right| &\le |\sin(\phi_{as}t_2) - \sin(\phi_{as}t_1)|^\beta \\
&= 2^\beta \left|\cos\left(\frac{\phi_{as}}{2}(t_2 + t_1)\right)\right|^\beta \left|\sin\left(\frac{\phi_{as}}{2}(t_2 - t_1)\right)\right|^\beta \\
&\le 2^\beta \left|\sin\left(\frac{\phi_{as}}{2}(t_2 - t_1)\right)\right|^\beta \\
&< \phi_{as}^\beta|t_2 - t_1|^\beta.
\end{aligned}
$$

Thus, combining this inequality with (4.30), we obtain that

$$|g(t_2) - g(t_1)| \le \left[\left(\frac{\pi}{2}\right)^{1-\beta} + 1\right](1 + \beta)|c_{as}|\phi_{as}^{1+\beta}|t_2 - t_1|^\beta. \tag{4.32}$$

But we know from (4.6) that, for all $k \ge 0$,

$$|g_{2k+1}| = s_{2k+1}^\beta \quad \text{and} \quad |g_{2k+2}| = |g_{2k+3}| = s_{2k+1}^\beta \frac{|g_{2k+3}|}{|g_{2k+1}|} \le s_{2k+1}^\beta.$$

As a consequence, we deduce using Table 4.2 that, for every interpolation interval,

$$|g_b - g_a| \le 2^\beta s^\beta$$

because the length s of each interval is equal to half that of the corresponding successful step. Using this inequality and (4.20), we obtain that

$$
\begin{aligned}
|c_{as}|\phi_{as}^{1+\beta} &\le \frac{\phi_{as}^\beta|g_b - g_a|}{(1 + \beta)[\sin(\theta_s)]^\beta \cos(\theta_s)} \\
&\le \frac{2^\beta \phi_{as}^\beta s^\beta}{(1 + \beta)[\sin(\theta_s)]^\beta \cos(\theta_s)} \\
&\le \left(\frac{\pi}{2}\right)^\beta \frac{2^\beta}{(1 + \beta)[\kappa_{\sin}]^\beta \kappa_{\cos}}
\end{aligned}
\tag{4.33}
$$

where we used the equality $\phi_{as}s = \theta_{as}$, (4.24), (4.26), and (4.29) to derive the last inequality. Hence, we deduce from (4.32) that, for x and y belonging to the same interpolation interval,

$$|g(x) - g(y)| \le \left[\frac{\pi}{2} + \left(\frac{\pi}{2}\right)^\beta\right]\frac{2^\beta}{[\kappa_{\sin}]^\beta \kappa_{\cos}}|x - y|^\beta \stackrel{\text{def}}{=} \tfrac{1}{2}L_\beta|x - y|^\beta. \tag{4.34}$$

Consider now $0 \leq x < y$ where x and y belong to different interpolation intervals and assume first that y belongs to the interpolation interval following that containing x. Then, if $z \in (x, y)$ is the junction point between the two successive intervals,

$$
\begin{aligned}
|g(x) - g(y)| &\leq |g(x) - g(z)| + |g(z) - g(y)| \\
&\leq \tfrac{1}{2} L_\beta |x - z|^\beta + \tfrac{1}{2} L_\beta |z - y|^\beta \\
&\leq L_\beta |x - y|^\beta
\end{aligned}
\tag{4.35}
$$

where we use the triangle inequality, (4.34) on each interval, and the fact that $u^\beta + v^\beta \leq 2(u + v)^\beta$ for all $u, v \in [0, 1]$.

Consider finally $0 \leq x < y$ where x and y belong to different interpolation intervals, where y does not belong to the interval following that containing x. Let us denote by r_x the smallest root of g larger than x and by r_y the largest root smaller than y. Note that the existence of these roots is guaranteed by the construction of the interpolating function f which ensures that stationary point occurs at the junction between to two interpolation intervals covering a single successful step. It is easy to verify that x and r_x must belong either to the same interpolation interval or to two successive intervals. The same is true of r_y and y, yielding that

$$
|x - r_x| \leq 1 \quad \text{and} \quad |r_y - y| \leq 1.
\tag{4.36}
$$

Moreover, using either (4.34) or (4.35), we have that

$$
|g(x) - g(r_x)| \leq L_\beta |x - r_a|^\beta \quad \text{and} \quad |g(r_y) - g(y)| \leq L_\beta |r_b - y|^\beta
$$

and we may deduce, using (4.36) and (4.31), that

$$
\begin{aligned}
|g(x) - g(y)| &\leq |g(x) - g(r_x)| + |g(r_y) - g(y)| \\
&\leq L_\beta \left((r_x - x)^\beta + (y - r_y)^\beta \right) \\
&\leq L_\beta (r_x - x + y - r_y)^\beta \\
&\leq L_\beta |y - x|^\beta
\end{aligned}
\tag{4.37}
$$

It then results from (4.34), (4.35) and (4.37) that $g(x)$ is Hölder continuous and AS.2 is satisfied in our example. This is illustrated in Figure 4.3.

We also note that, because of (4.25), the definition of θ_{as}, the fact that $\frac{1}{2} < 1$, (4.6) and the decreasing nature of $\{\|g_k\|\}$, we have that, for every interpolation interval,

$$
\phi_{as}^\beta > \left(\frac{\kappa_\theta}{s} \right)^\beta \geq \frac{\kappa_\theta^\beta}{|g_a|} \geq \frac{\kappa_\theta^\beta}{|g_0|}.
$$

Hence (4.19) and (4.33) ensure that $g(x)$ is bounded above for $x \geq 0$, which, together with the inequalities $f(x_k) \geq f_\infty > -\infty$, $s_k \leq 1$ and the mean-value theorem applied in each interval, guarantees that there exists a constant $f_{\text{low}} > -\infty$ such that $f(x) \geq f_{\text{low}}$ for all $x \geq 0$. Thus AS.3 holds with $f_{\text{target}} = -\infty$ and $f_* = f_{\text{low}}$. Moreover, AS.4 trivially follows with $\kappa_{gl} = 0$, $\kappa_{gu} = 1$ and $\epsilon_* = \epsilon$. AS.5 is satisfied by construction with $\kappa_B = 0$ since we set $B_k = 0$ for all $k \geq 0$.

We therefore conclude that all our assumptions hold and that our example is valid, in that Algorithm 2.1 applied on $f(x)$ with arbitrarily small $\tau \in (0, 1)$ in the case where $p > 1 + \beta$ needs at least

$$
2 \left(\left\lfloor \epsilon^{-\frac{1+\beta}{\beta + \tau(1+\beta)}} \right\rfloor - q \right)
$$

Figure 4.3: The shape of the function $|g(x) - g(y)|/|x - y|^\beta$ for the interval spanned by the first 8 successful iterations for $\beta = 0.45$, $p = 2.1$, $\tau = 0.001$, $\eta_1 = 0.6$ and $q = 3$

iterations (and function evaluations) to obtain an iterate x_ϵ such that $\|g(x_\epsilon)\| \le \epsilon$. Since q is independent of ϵ, this shows that the complexity bound stated by part (ii) of Theorem 3.10 is essentially sharp.

5 Discussion

Which power of $\epsilon_* < 1$ dominates in the complexity bounds of Theorem 3.10 is illustrated in Figure 5.4 as a function of p and β. It is interesting to note that the worst-case evaluation complexity of our general class of regularized method does depend on the relative values of p and β. Observe also that, when $\epsilon_* < 1$, $\epsilon^{-\frac{p}{p-1}} > \epsilon^{-(1+\frac{1}{\beta})}$ in the triangle for which $1 + \beta \ge p$ and $p \le 2$.

    As can be seen in this figure, there is little incentive for a user to choose a regularization power $p < 2$, at least from the worst-case complexity point of view (not to mention the need of AS.4). It is also interesting to observe that, if $p \ge 2$, the complexity no longer depends on the precise value of p, but only depends on the smoothness of the objective function as measured by the Hölder exponent β (whose knowledge is not required a priori). In that sense, the algorithm adapts itself to the problem at hand without any further user tuning (see also the "universal" gradient methods by Nesterov for the convex case [14]).

    If $\epsilon_* \ge 1$ (that is if either $\epsilon \ge 1$ or $\kappa_{gl} \ge 1$), the results above simplify because negative powers of ϵ_* are bounded above by one. As a consequence, all terms involving such powers (which we kept explicit in the analysis for $\epsilon_* < 1$) are absorbed in the constants, and the complexity bounds of Theorem 3.10 essentially reduce to multiples of the difference $f(x_0) - f_*$.

    Note also that Lemma 3.1 allows us to equate $\beta > 1$ with $\beta = 1$ and $\kappa_{gl} = \|g(x_0)\|$. In this case, either $\epsilon_* = \epsilon > \|g(x_0)\|$ and Algorithm 2.1 stops at iteration 0, or $\epsilon_* = \|g(x_0)\|$ and the bounds of Theorem 3.10 become independent of ϵ, resulting in a bound on the number of
Figure 5.4: Worst-case evaluation complexity as a function of β and p in the cases where $\epsilon_* < 1$

iterations and evaluations directly proportional to $f(x_0) - f_{\text{target}}$, as expected.

We conclude by observing that the theory presented above recovers known results (see [5] for the case where $p = 3$ and $\beta = 1$ and [13, 6] for the case where $p = 2$ and $\beta = 1$); these cases correspond to the thick dots in Figure 5.4.
