Abstract

Train timetable rescheduling — the practice of changing the routes and timings of trains in real-time to respond to delays — can help to reduce the impact of reactionary delay. There are a number of existing optimisation models that can be used to determine the best way to reschedule the timetable in any given traffic scenario. However, many of these models do not adequately account for the acceleration and deceleration required for trains to achieve the rescheduled timetable. The few models that do account for this are overly complex and cannot be solved to optimality in sufficiently short times. In this study, we propose a new model for train timetable rescheduling that uses statistical methods and historical data to parsimoniously take train speed into account. The model is tested using a new set of instances based on real data from Derby station in the UK. We show that the improved accuracy of the proposed model comes with little to no trade-off in terms of run time compared to fixed speed timetable rescheduling models.

Keywords— railway optimisation, timetable rescheduling, speed profile, variable-speed.

1 Introduction

Reactionary delays are a significant problem in railway systems. These are delays that are caused by the knock-on effect of prior delays. In 2019, reactionary delays were responsible for 64.35% of total train delay minutes in Great Britain (statistic provided by Network Rail). The problem is particularly acute in large, busy station areas, where the limited capacity of the station creates a bottleneck.

Reactionary delays can be reduced by performing *timetable rescheduling*. Timetable rescheduling involves changing the planned schedules of trains in real-time to respond to unexpected delays. The aim of solving the Train Timetable Rescheduling Problem (TTRP) [Cacchiani

et al., 2014] is to find a way to reschedule the timetable that is achievable in practice and optimises some objective. TTRP models must take into account the *speed profile* of each train, which describes how the velocity of the train changes over time. If the speed profiles of trains are not modelled with sufficient accuracy, then TTRP solutions may perform worse than expected in practice. This has been demonstrated by Hosteins et al. [2019] using a detailed railway simulator. Lack of attention to speed profile modelling is therefore a significant risk to the validity of TTRP models.

The focus of this paper is the development of techniques for improving the modelling of speed profiles in TTRP models. In particular, the model proposed by Reynolds et al. [2020] is extended to include approximate train speed trajectories. Using a new set of realistic instances from Derby station in the UK, we show that this extended model can be solved to optimality in times comparable to the original model of Reynolds et al. [2020].

1.1 Problem Description

The Train Timetable Rescheduling Problem (TTRP) is solved following a disturbance to the timetable to calculate an optimal rescheduled timetable. This disturbance could consist of any set of delays that results in two trains requiring the same infrastructure at the same time (a *conflict*), making the current timetable infeasible. The rescheduled timetable — the solution to the TTRP — consists of a new route and set of timings (i.e. a new schedule) for each controlled train. Controlled trains are those that are forecast to be inside a defined area of track during a time horizon. New routes can involve stopping at different platforms from those originally planned, taking different approaches to planned platform stops, or cancelling stops altogether. The rescheduled timetable must contain no conflicts and therefore be capable of being carried out in practice, respecting the constraints of the signalling system. A solution is considered optimal if it maximises a utility function representing the preferences of Network Rail, the infrastructure manager in Great Britain. This is modelled as the total weighted utility over all train stops which are carried out, where at each stop the utility disfavours lateness, platform change and cancellation.

1.2 Structure of the Paper

Key concepts and relevant literature are reviewed in Section 2. Section 3 provides an overview of our proposed model and approach to modelling speed profiles. Methods for estimating traversal times are developed in Section 4. The model is then described in full in Section 5. Section 6 presents a computational study. Section 7 contains our conclusions and suggestions for future

2 Literature Review

Many different variants of the TTRP have been described in the literature. As a result, many different models have been proposed. Much of this research is detailed in the surveys of Cacchi-ani et al. [2014], Fang et al. [2015] and Corman and Meng [2015]. The *speed profile* of a train k is a continuous, non-linear function $v^k : [0, T] \rightarrow \mathbb{R}^+$ mapping each time t in the time horizon to the velocity $v^k(t)$ of the train at that instant. However, it is computationally impractical to optimise such a function for each train within a TTRP model. Our literature review will focus specifically on the ways in which train speed profiles have been approximated in TTRP models.

2.1 Fixed-speed and Variable-speed Models

Timetable rescheduling models can be classified as either *fixed-speed* or *variable-speed* models, depending on how speed profiles are modelled. An early reference to this terminology appears in [Cordeau et al., 1998, p. 393-396]. In fixed-speed models, speed profiles are implicitly modelled via the specification of a fixed minimum time that is required for each train to traverse each segment of railway track. These are called *minimum traversal times* because whilst trains are permitted to stop in any segment and hence spend longer than this minimum time, they cannot traverse the segment in a shorter amount of time. In fixed-speed models, minimum traversal times are pre-computed and apply regardless of the rescheduling actions that are proposed by the model or the speed profiles required in practice to achieve them. The fixed minimum traversal time of a segment may be the same for every train that traverses it. Alternatively, minimum traversal times may be calculated based on assumptions about the likely speed profile of a particular train carrying out its originally planned schedule. There are many examples of fixed-speed TTRP models, such as those presented by Corman et al. [2010], Meng and Zhou [2014], Pellegrini et al. [2014], Lamorgese et al. [2016] and Reynolds et al. [2020].

Fixed-speed models can sometimes produce solutions that are not achievable in practice. The reason for this is illustrated in Figure 1. Consider a train traversing three segments of track r_0 , r_1 and r_2 in sequence. If the train maintains a constant velocity, then the traversal times of the segments are t_{r_0} , t_{r_1} and t_{r_2} , respectively. Now suppose that the train comes to an unplanned stop in r_2 as a result of a rescheduling decision. A fixed-speed model will use the same fixed traversal times for each segment, with an additional waiting time of D in r_2 . However, in reality

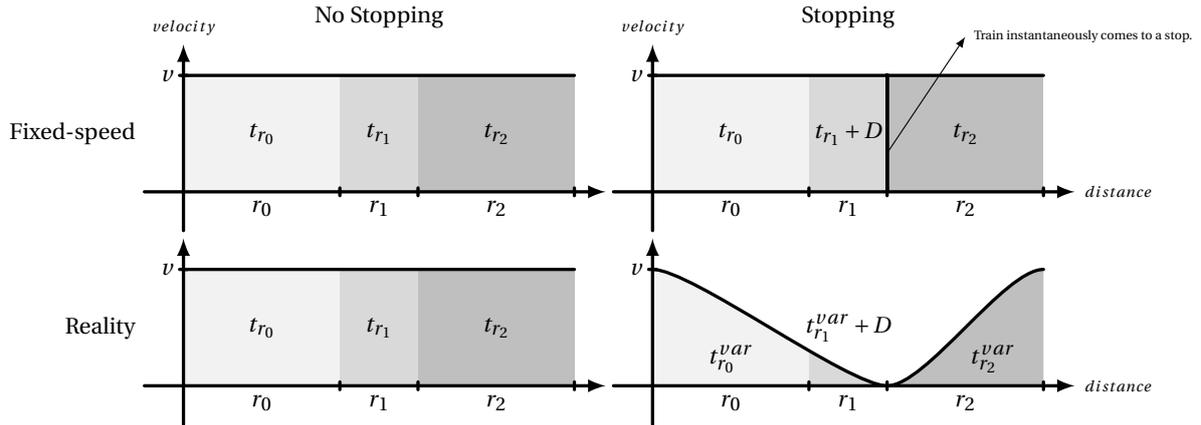

Figure 1: An example of how the speed profile assumptions made in fixed-speed models compare to actual speed profiles. The plots depict a scenario in which a train traverses r_0 , r_1 and r_2 in sequence. On the left, the train does not stop; on the right, the train stops in r_2 .

the train’s speed profile must change so that it decelerates in order to stop, and accelerates 92 afterwards. This changes the real traversal times to $t_{r_0}^{var} > t_{r_0}$, $t_{r_1}^{var} > t_{r_1}$ and $t_{r_2}^{var} > t_{r_2}$. As 93 a result, the disparity between actual traversal times and the traversal times in a fixed-speed 94 model can be large. The negative effects of these disparities have been observed by Hosteins 95 et al. [2019]. They find that high-quality solutions produced by the fixed-speed optimisation 96 model of Pellegrini et al. [2014] do not always perform well when tested using a microscopic 97 railway simulation. They find that the extent of the issue is dependent on the granularity of 98 the model and the objective function used. 99

Variable-speed models attempt to overcome this problem by making traversal times depen- 100 dent on rescheduling actions. One way of achieving this is by iterating between a fixed-speed 101 rescheduling model and a speed profile optimisation model. Speed profile optimisation models 102 are detailed kinetic models that optimise the speed profile of a single train carrying out a fixed 103 schedule to minimise journey times or energy consumption. The relevant literature is sum- 104 marised by Yang et al. [2016], Scheepmaker et al. [2017] and Yin et al. [2017]. The traversal 105 times in the fixed-speed model are updated in each iteration according to the speed profiles 106 required to achieve the rescheduling solution that it produced in the previous iteration. This 107 iterative approach has been explored by both D’Ariano et al. [2007b] and Mazzarello and Ot- 108 taviani [2007]. Whilst iterative approaches laudably avoid the need for fundamental changes 109 to rescheduling models, they do not guarantee convergence to a solution that is feasible for 110 both models. Moreover, it can be time consuming to solve a fixed-speed model multiple times, 111 which makes the iterative approach especially unsuitable for the real-time environment in which 112 rescheduling takes place. 113

To overcome these problems with the iterative approach, speed profiles can be modelled directly within the rescheduling model. Several authors have suggested simple ways to account for the disparity that arises between fixed traversal times and actual traversal times following unplanned stops (as described in the example above). Hosteins et al. [2019] suggest adding a fixed additional time to the traversal time of any segment in which a train comes to a stop. Rodriguez [2007] suggests adding an additional time to the traversal time of the subsequent segment that depends linearly on the amount of time the train stops for. Whilst these methods have the merit of being simple and leading to linear constraints, they are clearly very approximate. In reality, the additional acceleration time is not a fixed constant, and it is not linear in the amount of stopping time. Lusby et al. [2013] show that speed profiles can be modelled within the subproblem of a model solved using column generation. This allows speed profiles to be modelled in a more sophisticated way using kinematic formulae. A similar column generation approach to that of Lusby et al. [2013] is used in this paper. However, speed profiles are modelled differently to overcome some specific problems that are discussed in Section 4.

A different approach is to select the speed profile of each train in advance and then disallow rescheduling actions that would compromise their validity. This approach, taken by both Corman et al. [2009] and Caimi et al. [2012], is suitable if a *green wave* policy is in operation. A green wave policy dictates that trains must only come to a stop within stations, thereby reducing unnecessary braking and acceleration and saving energy. However, it does not solve the problem of modelling speed profiles within the general TTRP, where trains may come to a stop anywhere on the track network.

More recently, different ways of integrating the TTRP with speed profile optimisation have been proposed by Xu et al. [2017], Zhou et al. [2017] and Luan et al. [2018a,b]. These models seek to determine the actual speed profile to be used by each train simultaneously with carrying out timetable rescheduling. The principal benefit of this integration is that by solving the two problems simultaneously, solutions with better overall quality can be achieved. However, to integrate the problems it is necessary to assume that precise real-time information about both train speed profiles and signalling states are centrally available, and that both can be centrally and automatically controlled. In other words, these models are only useful for railways in which the functions of *traffic control* and *train operation* are integrated (see [Yin et al., 2017, p. 568] for a discussion of this integration). They are typically only integrated on new and expensive high-speed lines. As a result, the integration of the TTRP with speed profile optimisation is inappropriate for practical use on the majority of railways.

2.2 Physics-based and Data-driven Models

147

Each of the models proposed by Lusby et al. [2013]; Xu et al. [2017]; Zhou et al. [2017]; Luan
et al. [2018a,b] are *physics-based*. This means that traversal times of track segments are derived
from kinetic speed profile modelling. Track segment distances and train speed capabilities are
combined with assumptions about the tractive force applied by the driver to calculate traversal
times. This kind of kinetic modelling has traditionally been used to estimate running times for
timetable construction and evaluation — an introduction to this topic is provided by Brünger
and Dahlhaus [2014]. Luan et al. [2018a,b] incorporate much of this kinetic modelling into
a mixed-integer non-linear programming formulation, and propose two heuristics for solving
a linearised version of the formulation. Heuristics are used because realistic instances cannot
be solved to optimality in suitable computation times. Both Xu et al. [2017] and Zhou et al.
[2017] discretise velocity, thus avoiding direct representation of the non-linear kinetics of train
motion. Xu et al. [2017] extend the Alternative Graph model (see D’Ariano et al. [2007a])
to incorporate speed-dependent traversal times. Zhou et al. [2017] propose a time-space-speed
network model for the offline train timetabling problem on a high-speed line with power supply
constraints.

161
162

The physics-based approach to traversal time modelling has practical disadvantages. Detailed
information about the physical properties of the track and trains is required, despite the fact
that it can be hard to obtain. For example, Luan et al. [2018b] use physical parameters for
the resistance between train and track that are individualised for each train and block section.
Finding this information isn’t simply a data collection exercise: many parameters need to first
be estimated and then calibrated within the overall model. Although sophisticated methods
such as those of Bešinović et al. [2013] have been developed to estimate the parameters used in
physical speed profile calculations, each estimated parameter is still subject to uncertainty. The
effect of this uncertainty on rescheduling models is not well understood. Our model bypasses
the need for these physical parameters, and is therefore significantly less onerous to test and
deploy. It is also easier to adapt to changes in infrastructure than physics-based models, since
any changes will be reflected in the data and can be used to update traversal times. These
are significant advantages given that practical implementations of the TTRP are still rare (see
Lamorgese et al. [2018] for a description of the state of implementation).

173
174
175
176

There are also important modelling disadvantages to using the physics-based approach. In a
physics-based model, the modeller must make assumptions about which speed profiles should
be feasible. For example, Lusby et al. [2013] and Zhou et al. [2017] assume constant rates

177
178
179

of acceleration over each section of track and each time interval, respectively. Lusby et al. [2013] allow trains to travel at any real-valued speed below the speed limit, whilst Zhou et al. [2017] and Xu et al. [2017] allow trains to travel only at one of a few pre-defined speeds in each block section. Zhou et al. [2017] allow trains to transition between any two speed levels provided limits on the acceleration and deceleration capabilities of the train are respected, whilst Xu et al. [2017] allow trains to transition only between adjacent speed levels. All of these approaches to constraining speed profiles run the simultaneous risks of both eliminating perfectly reasonable speed profiles from the feasible space, and including many speed profiles that are very unlikely to arise in practice.

In this paper, we avoid these problems by taking a *data-driven* approach. This terminology refers to the fact that we infer traversal times from historical observations, leading to an innovative synthesis of statistical techniques with optimisation. Our data-driven approach provides a natural way to model traversal times that reflects speed profiles that have actually arisen in the past on the parts of track that are modelled. Rather than making assumptions about how to constrain speed profiles, our approach allows the data to speak for itself. Results for our application show that the use of more than one traversal time is justified by the data on only a subset of the routes. This highlights an additional advantage of our data-driven approach. It is able to target increased model complexity (a higher number of possible traversal times) at parts of the track where it can be best justified by the data. The result is a significantly more parsimonious model than any of the physics-based models that have been mentioned.

2.3 Contributions

The contributions made by this paper can be summarised as follows:

1. We propose a new variable-speed model for the TTRP in complex station areas. The model utilises a time-space-type graph to approximate train speed profiles.
2. We show how the application of statistical methods to historical data can be used to model traversal times in a variable-speed model. This data-driven approach results in a parsimonious model that is less onerous to test and deploy than existing physics-based models. Moreover, it avoids the need to make restrictive assumptions about speed profiles.
3. We present a new set of instances based on real data from Derby station in the UK.
4. We show that these instances can be solved to optimality or provably near to optimality in times suitably short for real-time operations. In particular, the solving times are comparable with the fixed-speed model proposed by Reynolds et al. [2020].

3 Model Overview

212

This paper presents a model for the TTRP that is based on a time-space-type (TST) graph. 213
This is a directed graph $G = (N_0 \cup \{source, sink\}, A)$ that models the state of each train over the 214
time horizon using a path from the *source* node to the *sink* node. Each node in N_0 represents 215
a state in which a train could be, whilst each arc represents a possible transition between these 216
states. 217

Each node in N_0 corresponds to a combination (r, t, v) of a route r , a time interval t and a speed 218
profile type v . These are defined as follows: 219

- A *route* is a short length of track that runs from one railway signal to another. The 220
controlled area of track is formed of a set of routes N_r , that can be modelled as a route 221
graph $G_r = (N_r, A_r)$, where the arcs in A_r represent feasible route transitions. Figure 2 222
shows the route graph for an area centred on Derby station. 223
- *Time intervals* are periods of time, each of length 10 seconds, that together form a parti- 224
tion \mathcal{T} of the time horizon. The time horizon begins at the time the model is solved and 225
lasts for one hour. 226
- Each traversal of a route $r \in N_r$ by a train is modelled as having a *speed profile type*. The 227
minimum number of time intervals L_r^v required to traverse r is dependent on the speed 228
profile type v that is used. Whilst there are three general types $N_v = \{v_0, v_1, v_2\}$, the 229
possible speed profile types for any given route r are $N_r^v \subseteq N_v$. The definition of these 230
speed profile types and the calculation of the traversal times is the subject of Section 4. 231

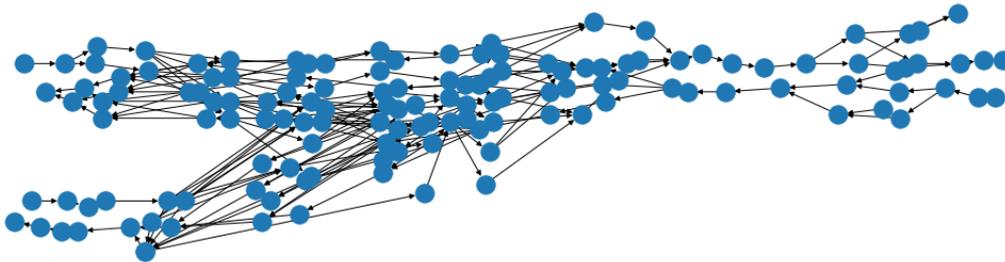

Figure 2: The route graph G_r for the area centred on Derby station that is used in our computational experiments.

3.1 Example TST Graph

232

A small explanatory example of a TST graph is depicted in Figure 3. In this example, the route graph is given by

$$N_r = \{AB, BC, CD, DE\} \text{ and } A_r = \{(AB, BC), (BC, CD), (CD, DE)\}$$

and the time horizon $\mathcal{T} = \{0, \dots, 7\}$ consists of eight time intervals. There are three speed profile types, v_0 , v_1 and v_2 , although type v_2 is not possible in routes CD or DE ($N_v^{CD} = \{v_0, v_1\} = N_v^{DE}$). Type v_0 corresponds to stopping, since the arcs join nodes corresponding to the same route at consecutive time intervals. The traversal times of type v_1 are $L_{AB}^1 = 3$, $L_{BC}^1 = 2$ and $L_{CD}^1 = 2$. The traversal times of type v_2 , $L_{AB}^2 = 1$ and $L_{BC}^2 = 1$, are shorter. The graph G contains arcs allowing movement between speed profile types, but movement between types v_0 and v_2 is not possible. The thick blue line is an example *source-sink* train path in G . It corresponds to a sequential traversal of all routes, with AB and CD traversed with speed profile type v_1 , BC with type 2, and the train coming to a stop in DE .

241

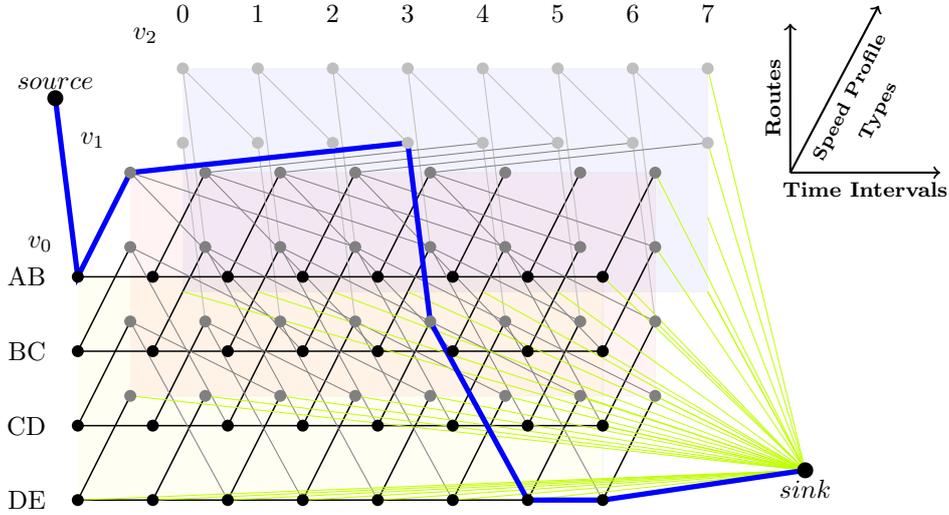

Figure 3: An example of a time-space-type graph.

A solution to the problem (i.e. the new schedule) comprises one *source-sink* path in G for each controlled train $k \in \mathcal{K}$. This path completely describes the sequence of routes to be traversed by k , the time intervals in which each route traversal begins and the speed profile of each traversal.

3.2 Speed Profile Types

246

In fixed-speed models, the traversal time of a route $r \in N_r$ is represented by a single value L_r .
 Trains are usually permitted to come to a stop on any route. As a result, L_r is merely the
 minimum traversal time because a train may spend longer than L_r in route r by stopping in it.
 Whilst L_r may depend on the train, route or pre-planned speed profile, it does not depend on
 the speed profile required to achieve the rescheduled solution. We refer to stopping (denoted
 by v_0) and ordinary traversal (denoted by v) as *speed profile types*. Figure 4 visualises the fact
 that both stopping and ordinary traversal are possible on any route, regardless of which type
 occurred on the previous route.

247

248

249

250

251

252

253

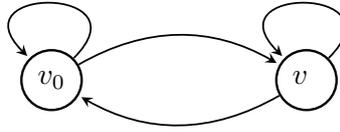

Figure 4: Speed profile type graph for a fixed-speed model.

254

Our approach is a natural extension of this idea to use two different traversal times L_r^1 and
 L_r^2 (with $L_r^1 > L_r^2$) corresponding to two speed profile types v_1 and v_2 , respectively. The
 traversal time that is required for a train to traverse r will be either L_r^1 or L_r^2 , depending on the
 speed profile required to perform the rescheduled solution. The resulting model is, therefore, a
 variable-speed model. In particular, the speed profile type used by a train on a given route is
 constrained to be adjacent in the type graph G_v (see Figure 5) to the type used on the preceding
 route. Because $(v_0, v_2), (v_2, v_0) \notin A_v$, this constraint prevents trains from using the faster speed
 profile type v_2 and stopping v_0 on consecutive routes. The rationale is that fast speeds and
 stopping must be separated by periods of acceleration or deceleration that involve slower speeds.
 Note that this assumption is somewhat similar to the constraint of Xu et al. [2017] stating that
 the speed levels on consecutive block sections must be at most one level apart. However, we
 use speed profile types instead of physically defined speed levels (e.g. 250–300 km/h).

4 Traversal Time Estimation

267

It is important to address the question of how to calculate the variable traversal times L_r^1 and L_r^2 for each route r . This is because the extent to which these values are representative of the actual traversal times of trains with different speed profiles is a major determinant of whether the solutions produced by the model are achievable in practice. The calculation of traversal times is therefore an inextricable part of the modelling methodology.

In fixed-speed models, traversal times can be estimated using classical running time estimation techniques — see [Brünger and Dahlhaus, 2014] for a review. Stochastic running time estimation methods have also been proposed for use in timetable simulation [Yuan and Medeossi, 2014]. However, the question of how to calculate traversal times for variable-speed TTRP models hasn't been adequately addressed. This task poses several unique challenges that straddle the topics of running time estimation and timetable rescheduling. In our case, two times L_r^1 and L_r^2 that represent trains with different speed profiles are required. These must be meaningful in the sense that it should be rare or impossible for a train to use types v_0 and v_2 in consecutive routes, but possible for any other combination to occur. An additional challenge is posed by the discrete nature of time in the model, meaning that times must correspond to a whole number of time intervals. Finally, routes in station areas are often much shorter than the distances over which running times are typically calculated.

Our approach involves estimating traversal times based on historical data. The data that is used was collected by a *Train Describer* over a seven month period. A Train Describer is a real-time information system that records the sequence of routes traversed by each train and the number of seconds spent in each one.

4.1 Method 1: Estimating a Single Time (Fixed-Speed)

289

First we summarise the method employed by Reynolds et al. [2020] for estimating a single traversal time L_r for a given route $r \in N_r$ in a fixed-speed model. The data used is $\mathbf{y}^r = (y_1^r, \dots, y_{n_r}^r)$, a vector containing the number of seconds spent in r by n_r different trains. Unimodal statistical distributions are generally not appropriate for modelling \mathbf{y}^r . This is because the times arise from different processes according to the speed profile used by a train in r . By modelling each speed profile type as a different process, we can model \mathbf{y}^r as a mixture of unimodal distributions. The speed profile type of each observation is unobserved, but this can be estimated by fitting a mixture model. Specifically, we fit a Gaussian Mixture Model (GMM) to each \mathbf{y}^r using the Expectation-Maximisation (EM) algorithm. This is a model-based clustering technique

that identifies groups of historical times (called *clusters*) that approximately follow a Gaussian 299
distribution. An introduction to GMMs and the EM-algorithm is provided by Bouveyron et al. 300
[2019]. 301

To fit a GMM to \mathbf{y}^r , the number of clusters (each corresponding to a speed profile type) must 302
be specified in advance. The appropriate number is different for each route. For example, on 303
the open line where trains rarely travel below the line speed there is often only one process 304
occurring and therefore a single cluster is appropriate. Conversely, up to three different speed 305
profile types are discernible on many routes within stations. To decide the number of clusters, 306
we fit three models with 1, 2 and 3 clusters respectively, and choose the model that optimises 307
the Bayesian Information Criterion [Bouveyron et al., 2019, p. 51]. 308

In the fixed-speed model, a single time L_r must be chosen for each route from the fitted mixture 309
distribution. The cluster with the smallest mean is selected, since this reflects the times of trains 310
travelling close to the speed limit. From this component, the mean is rounded up to the nearest 311
number of whole time intervals to produce L_r . Whilst rounding introduces approximation 312
error, rounding up ensures that the feasibility of a solution to the model is not compromised. 313
An example of the result of this clustering process is shown in Figure 6. 314

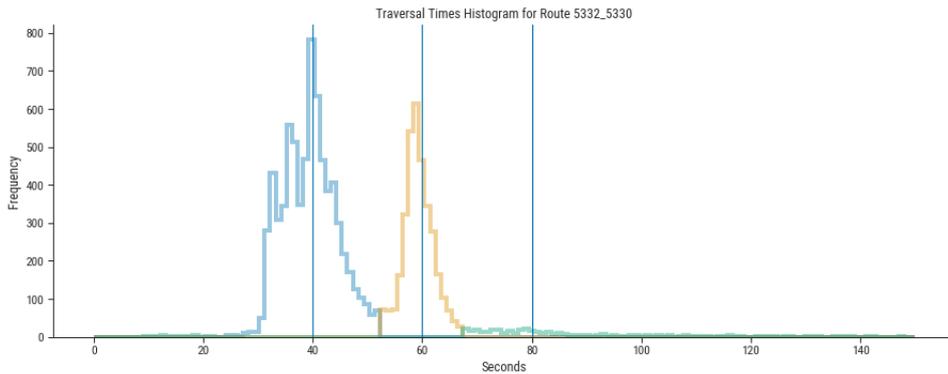

Figure 6: The histogram of historical traversal times for route 5332_5330. The three clusters 315
identified are shown in different colours. The rounded mean of each cluster is shown as a vertical 316
line. The left-most vertical line (40 seconds, or $L_r=4$) is used as the final estimate of the route 317
traversal time. 318

4.2 Method 2: Extension to Multiple Times (Variable-Speed) 315

The method presented in Section 4.2 can be extended to produce two traversal times, L_r^1 and 316
 L_r^2 , for routes with three clusters. The traversal times L_r^1 and L_r^2 are calculated by taking the 317
smallest and second smallest means of the clusters, respectively, and rounding up to the nearest 318
whole number of time intervals. This allows more speed profile types to be represented in the 319
model. Trains travelling close to the speed limit have a traversal time of L_r^1 , whilst trains that 320

accelerate/decelerate or coast below the speed limit have a traversal time of L_r^2 . Observations 321
in the third cluster are discarded, since these correspond to stopping, and that is not modelled 322
using a traversal time. 323

Given the assumptions made about how clusters correspond to speed profile types, we expect to 324
observe that when trains traverse two routes consecutively, the respective traversals are rarely of 325
types $v_0 \rightarrow v_2$ or $v_2 \rightarrow v_0$. This is because these transitions represent an abrupt change between 326
stopping and a fast speed within the space of a single route. To test whether this is the case, 327
a model of transitions between different clusters is created using historical data from the Train 328
Describer. For each historical train journey j , this transition data consists of both the sequence 329
 $(r_1^j, \dots, r_{n_j}^j) \in (N_r)^{n_j}$ of routes traversed, and the corresponding sequence $(t_1^j, \dots, t_{n_j}^j) \in \mathbb{R}_+^{n_j}$ of 330
traversal times for each route in seconds. Since the clustering process classifies each traversal 331
time t_i^j as belonging to a particular speed profile type, the journey can also be represented as a 332
sequence $(i_1^j, \dots, i_{n_j}^j) \in \{v_0, v_1, v_2\}^{n_j}$ of speed profile types. 333

In order to test the suitability of the clustering method, we model the speed profile type se- 334
quences probabilistically using a discrete Markov chain $(X_t)_{t \in \mathbb{N}}$ with state space $N_v = \{v_0, v_1, v_2\}$. 335
This means that for each time step $t \in \mathbb{N} = \{0, 1, 2, \dots\}$, X_t is a discrete random variable taking 336
values in N_v , such that 337

- **Markov Property** 338

$\mathbb{P}(X_{t+1} = i_{t+1} | X_t = i_t, \dots, X_0 = i_0) = \mathbb{P}(X_{t+1} = i_{t+1} | X_t = i_t)$ for any $t \geq 1$ and $i_t \in N_v$. 339

In our application, the Markov property means that the conditional probability of a train 340
using a speed profile type, given the types used on all previous route traversals, only 341
depends on the type used on the most recently traversed route. 342

- **Time homogeneous** 343

$\mathbb{P}(X_{t+1} = j | X_t = i) = \mathbb{P}(X_t = j | X_{t-1} = i)$ for any $t \geq 1$ and $i, j \in N_v$. 344

This means that the probability of transitioning from state i to j is independent of t , and 345
we denote this transition probability by p_{ij} . 346

The transition probabilities of this Markov chain can be inferred from the data. If n_{ij} is the 347
number of times j immediately follows i in a speed profile type sequence for a train journey in 348
the data, then p_{ij} is estimated by 349

$$p_{ij} = \frac{n_{ij}}{\sum_{m \in N_v} n_{im}}. \quad (1)$$

The clustering and transition probabilities were calculated using data from Derby station, and 350

the estimated transition probabilities are shown in Figure 7. Whilst $p_{v_0v_2} = 0.01$ is small, which is expected, $p_{v_2v_0} = 0.21$ is higher than expected. It would be problematic to disallow transitions from v_2 to v_0 in our optimisation model when the historical data shows that this occurs after as many as 21% of type v_2 traversals.

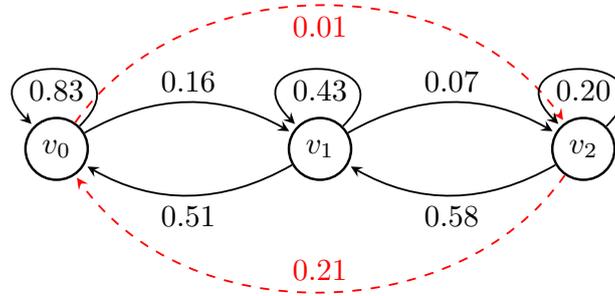

Figure 7: The Markov chain $(X_t)_{t \in \mathbb{N}}$, with estimated transition probabilities shown. Probabilities are rounded to two decimal places.

The higher than expected value of $p_{v_2v_0}$ could result from inadequacies in the clustering methodology that lead to misclassification of traversal times. One particular concern is that the Gaussian distribution may not be appropriate to model clusters. Another possibility is that distinct and meaningful clusters do not exist for some routes, or do not strongly correspond to speed profile types. A third possibility is that $p_{v_2v_0}$ is a poor estimate of the true transition probability. This could have arisen because for some routes, the cluster representing type v_2 has only a small number of data points. Finally, it may be inappropriate to assume that the Markov property holds. For example, the distribution of X_t given the values at each previous time step might be dependent on the value of X_{t-2} in a way that our probabilistic model has failed to reflect.

The potential problems that have been identified may affect different route transitions to different extents. It is possible to estimate transition probabilities $p_{ij}^{r,r'}$ for each route transition $(r, r') \in N_r$ separately. The probabilities $p_{ij}^{r,r'}$ are calculated in the same way as p_{ij} using formula (1) with one difference. The difference is that n_{ij} is replaced by n_{ij}^r , the number of observations of $(r, t) \rightarrow (r', t')$ in the transition data such that t is classified as type i and t' is classified as type j . The distributions of $p_{v_0v_2}^{r,r'}$ and $p_{v_2v_0}^{r,r'}$ over all route transitions $(r, r') \in N_r$ are shown in Figure 8. There is considerable variation across different route transitions, with $p_{v_2v_0}$ being acceptably low for some, and unacceptably high for others.

A severe limitation of this approach is that the transition data is used only for validation and not for the clustering, which is performed separately for each route. The transition data potentially

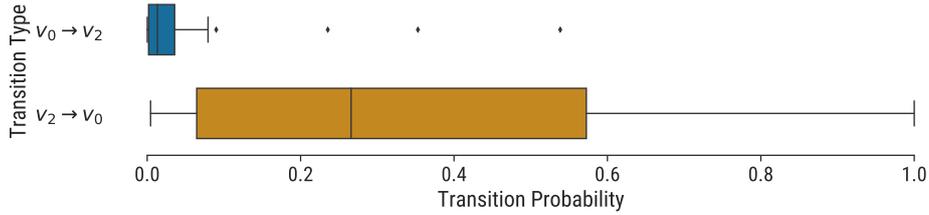

Figure 8: Boxplots showing the distribution of transition probabilities for types $v_0 \rightarrow v_2$ and $v_2 \rightarrow v_0$.

contains useful information that could be used when performing the clustering. For example, 375
a transition from a cluster of type v_2 to a cluster of type v_0 might indicate that the second 376
observation is misclassified and should be in cluster v_1 . Transition patterns also contain useful 377
information for selecting the number of clusters. This limitation is addressed in the next section, 378
where the full transition data is utilised. 379

4.3 Method 3: Transition-based Multiple Traversal Time Estimation 380

This method for estimating differentiated traversal times is designed to address the problems 381
identified with Method 2. It uses the full transition data to estimate the traversal times, 382
and it does not rely on the Markov property or assume that the data follows a Gaussian 383
distribution. 384

There are four main steps involved in Method 3. The first step is to identify, for each route 385
 $r \in N_r$, which observations from \mathbf{y}^r arise from a train coming to a complete stop in r (type v_0). 386
This is performed using traversal time data alone, without transition data. The distributions of 387
times recorded for each route are very heterogeneous, which makes using standard parametric 388
distribution fitting challenging. We therefore take an *ad hoc* approach. Any observation that 389
is longer than 120 seconds, or in the top 10% of observations is assumed to arise from a train 390
coming to a stop. These values (120 seconds and 10%) are selected using our familiarity with 391
the specific area being modelled. 392

The second step is to classify the remainder of the traversals as either type v_1 or type v_2 . This 393
is performed using the transition data alongside our classification of type v_0 transitions from 394
the first step. Specifically, a route traversal is classified as type v_1 if it occurs immediately 395
before or after another route traversal that has been classified as type v_0 . Conversely, route 396
traversals that are not adjacent to traversals of type v_0 are classified as type v_2 . This completes 397
the classification of each route traversal into a speed profile type. 398

The third step is to calculate the traversal times L_r^1 and L_r^2 using the classification from step 399

two. For $i = 1, 2$, the median l_r^i (in seconds) of type v_i observations is divided by 10 (the length 400
of a time interval) and rounded up to the nearest whole number to obtain L_r^i . Medians are 401
used because they are not unduly influenced by more extreme observations in each group. The 402
rounding process is necessary as a result of the discretisation of time in the TST graph. 403

The fourth and final step is to decide, for each route, whether the data supports using two 404
different traversal times or whether a single traversal time is more appropriate. Due to rounding, 405
routes r for which $l_r^1 - l_r^2 < 10$ have $L_r^1 = L_r^2$, so these should have only one traversal time i.e. 406
 $N_r^v = \{v_0, v_1\}$. For other routes, we check for statistical evidence that the true values \check{l}_r^1 and 407
 \check{l}_r^2 of the medians of groups v_1 and v_2 are significantly different (l_r^1 and l_r^2 are estimates of \check{l}_r^1 408
and \check{l}_r^2 , respectively). Mood's test for a difference in medians [Mood, 1950] is used to assess 409
this. A one-tailed test is performed at significance level 95% to test the null hypothesis that 410
 $\check{l}_r^2 = \check{l}_r^1$ against the alternative hypothesis that $\check{l}_r^2 > \check{l}_r^1$. When the null hypothesis is rejected, 411
both of the traversal times, L_r^1 and L_r^2 , are used. For the remaining routes, only L_r^1 is used 412
because there is a lack of statistical evidence that using a second traversal time is justified. An 413
illustration of the method for a particular route that is given two traversal times is shown in 414
Figure 9. The results of carrying out this method on all routes for Derby station are described 415
and discussed in Section 6.2. 416

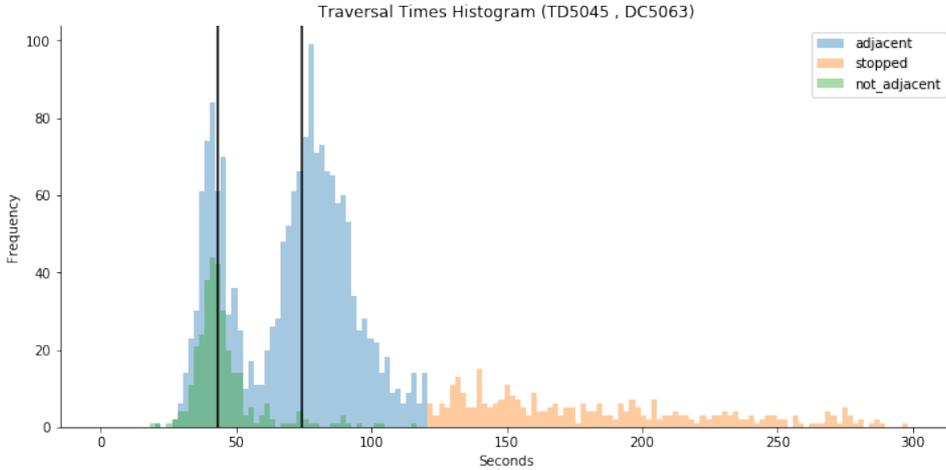

Figure 9: A histogram of historical traversal times for a particular route. The three estimated 417
groups are shown in different colours, and estimates for L_r^1 and L_r^2 are marked vertical lines. 418

5 Model Description and Solution Method 417

The results obtained from traversal time estimation are used to determine both the TST graph, 418
and sets of graph arcs that are used to model track capacity constraints. These objects, in turn, 419
are used to define a Mixed Integer Programming model for the TTRP that is solved using a 420

branch-and-price algorithm.

421

5.1 TST Graph

422

Recall from Section 3 that $G_r = (N_r, A_r)$ is the route graph and that $G_v = (N_v, A_v)$ is the speed profile type graph. The set of discrete time intervals is denoted by \mathcal{T} , whilst \mathcal{K} is the set of trains. For each route r , $N_r^v \subseteq N_v$ is the set of possible speed profile types for route r .

423

424

425

The TST graph is given by

$$G = (N_0 \cup \{source, sink\}, A),$$

where, in addition to the artificial source and sink, the nodes of G are given by

$$N_0 = \{(r, t, v) \in N_r \times \mathcal{T} \times N_v : v \in N_r^v\}.$$

The directed arc set $A = \bigcup_{i=1}^6 A_i$ of G consists of six different arc types. These six types and their interpretations are given below. Figure 10 shows an example arc of each different type in a small artificial example of G .

426

427

428

- $A_1 = \{(source, (r_0^k, a_0^k, v_0^k)) : k \in \mathcal{K}\}$

429

Entering from the source node to the first known position r_0^k of train k within the time horizon and modelled area, at time interval a_0^k , and speed profile type v_0^k .

430

431

- $A_2 = \{((r, t, v_0), (r, t + 1, v_0)) : (r, t, v_0) \in N_0 \text{ and } (r, t + 1, v_0) \in N_0\}$

432

Waiting in route r for one time interval when speed profile type is 0 (i.e. train is stopped).

433

- $A_3 = \{((r, t, v_0), (r, t, v_1)) : (r, t, v_0) \in N_0 \text{ and } (r, t, v_1) \in N_0\}$

434

Transitioning from speed profile type 0 (stopped) to type 1 so that the train can begin traversing r again.

435

436

- $A_4 = \{((r, t, v), (r', t + L_r^v, v')) : (r, r') \in A_r, (v, v') \in A_v,$

437

$$(r, t, v), (r', t + L_r^v, v') \in N_0, v \neq v_0\}$$

438

Traversing r with speed profile type v , and arriving in a successive route r' with speed profile type v' after a traversal time of L_r^v .

439

440

- $A_5 = \{((r, T, v), sink) : r \in N_r, v \in N_v\}$

441

Exiting to the sink node at the end of the time horizon.

442

- $A_6 = \{((r, t, v), sink) : \sigma^+(r) = \emptyset \text{ and } (r, t, v) \in N, v \neq v_0\}$

443

Exiting to the sink node from a node at the boundary of the area of track modelled. The train cannot exit whilst stationary.

444

445

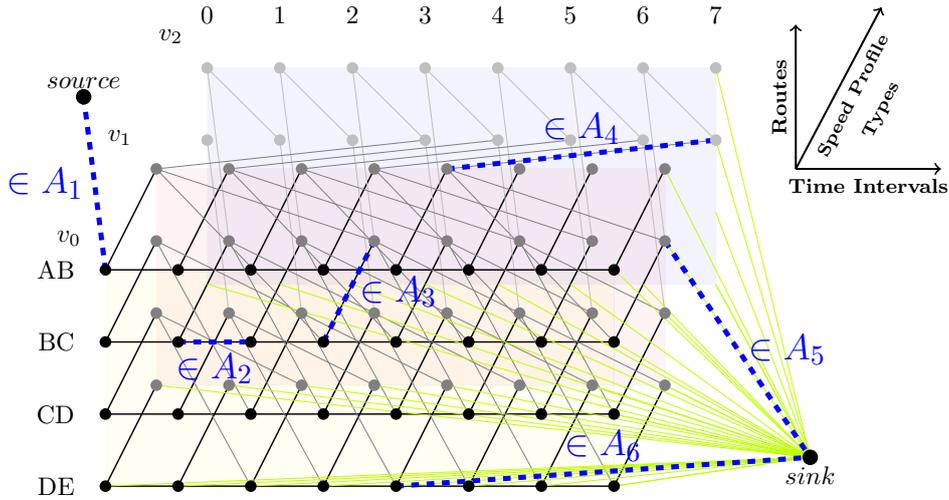

Figure 10: An example TST graph, with examples of arcs from different sets A_1 – A_6 labelled.

5.2 Track Capacity Constraints

446

A feasible solution to the TTRP is a set of *source-sink* paths in G , one for each train, that collectively satisfy the constraints of the signalling system. The signalling system is a safety system that limits track capacity and regulates train movements to avoid physical collisions. The type of signalling system modelled is a *sectional-release interlocking* system. This takes into account track subdivisions smaller than routes, called *track circuits*. All of the track circuits in a route are *locked* before a train may enter the route, and then *released* individually once the train has vacated each track circuit. Between locking and release, a track circuit cannot be locked by any other train. Because track circuits can form part of more than one route, the capacities of routes are not always independent.

447

448

449

450

451

452

453

454

455

The constraints induced by the signalling system can be modelled as capacities in the time-space-speed graph. Each pair $(r, t) \in N_r \times \mathcal{T}$ of one route and one time interval is regarded as a *time-space resource*. The capacity of these resources can be consumed by trains in two different ways: *occupying* and *banning*. Resource (r, t) is *occupied* by a train if and only if it has traversed r and at least one of the track circuits in r is still locked during time interval t . By contrast, a train *bans* a time-space resource (r', t) if it makes route r' unavailable during time interval t as a result of occupying (r, t) , where r is a distinct route with track circuits in common with r' . These terms are illustrated in more detail by Reynolds et al. [2020].

456

457

458

459

460

461

462

463

The capacity of each time-space resource (r, t) is subject to two constraints:

464

1. (r, t) cannot be occupied more than once; and

465

2. (r, t) cannot be both banned and occupied. 466

To enforce these constraints using the capacities of arcs in G , two sets of arcs, $A_{r,t}$ and $\bar{A}_{r,t}$, are 467
defined for each time-space resource (r, t) . These are defined such that a train path contains an 468
arc in $A_{r,t}$ if and only if it occupies (r, t) , whilst a train path contains an arc in $\bar{A}_{r,t}$ if and only 469
if it bans (r, t) . Reynolds et al. [2020] show how these sets can be constructed on a time-space 470
graph without speed profile types. We extend this to show how they can be constructed on the 471
TST graph G . Figure 11 visualises an example of a set $A_{r,t}$. 472

A train occupies (r, t) if and only if the *source-sink* path in G assigned to that train contains 473
a node from the set

$$W_{r,t} = \left\{ (r, t', v') : v' \in N_v^r, t' \in \{t - (L_r^{v'} + h_r) + 1, \dots, t\} \right\},$$

where h_r is headway time left for the release of route r to occur. To see this, suppose that a 473
train path contains such a node (r, t', v') . Then the track circuits of r cannot not all be released 474
until the train has traversed r , and the headway time h_r has elapsed. This cannot occur before 475
time interval $t' + L_r^{v'} + h_r \geq t - (L_r^{v'} + h_r) + 1 + (L_r^{v'} + h_r) = t + 1$, meaning that at least some 476
track circuits are still locked during time interval t . 477

A train bans (r, t) if and only if the *source-sink* path in G assigned to that train contains a 478
node from the set

$$\bar{W}_{r,t} = \left\{ (r', t', v') : r' \in S_r, v' \in N_v^r, t' \in \{t - t(r', v', r) + 1, \dots, t\} \right\},$$

where S_r is the set of routes distinct from r that share at least one track circuit with r . The 478
quantity $t(r', v', r)$ is the minimum number of time intervals between the track circuits of route 479
 r' being locked, and all of the track circuits common to r and r' being released, when r' is 478
traversed using speed profile type v' . This is given by

$$t(r', r) = \lceil \theta(r', r) L_{r'}^{v'} + h_{r'} \rceil,$$

where $\theta(r', r)$ is the proportion of the traversal of r' after which r is released. That quantity is 478
calculated from the track circuit data as described by Reynolds et al. [2020]. 479

Using the definitions of $W_{r,t}$ and $\bar{W}_{r,t}$, $A_{r,t}$ and $\bar{A}_{r,t}$ can be defined as:

$$A_{r,t} = \bigcup_{n \in W_{r,t}} \sigma^-(n) \setminus \bigcup_{n \in W_{r,t}} \sigma^+(n)$$

$$\bar{A}_{r,t} = \bigcup_{n \in \bar{W}_{r,t}} \sigma^-(n) \setminus \bigcup_{n \in \bar{W}_{r,t}} \sigma^+(n),$$

where $\sigma^-(n)$ and $\sigma^+(n)$ are used to denote the set of directed arcs of G entering a node n and leaving a node n , respectively. A path in G contains an arc in $A_{r,t}$ (respectively $\bar{A}_{r,t}$) if and only if it contains a node in $W_{r,t}$ (respectively $\bar{W}_{r,t}$). Therefore a path in G contains an arc in $A_{r,t}$ (respectively $\bar{A}_{r,t}$) if and only if it occupies (respectively bans) time-space resource (r,t) .

The track capacity constraints described above can be formulated in the following way. A set of *source-sink* paths in G is a feasible solution to the problem if and only if among all of the paths:

1. At most one arc in $A_{r,t}$ is used; and
2. If an arc in $A_{r,t}$ is used then no arcs in $\bar{A}_{r,t}$ are used.

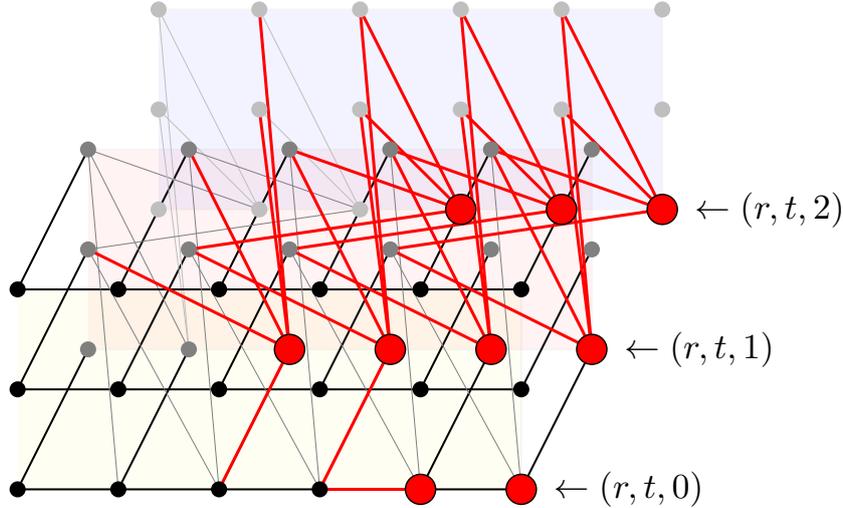

Figure 11: An illustration of $W_{r,t}$ and $A_{r,t}$ for a specific time-space resource $(r,t) \in N_r \times \mathcal{T}$ in an example graph G . The nodes in $W_{r,t}$ and arcs in $A_{r,t}$ are highlighted in red. The relevant times are $h_r = 1$, $L_r^0 = 0$, $L_r^1 = 2$ and $L_r^2 = 1$.

5.3 Antichain Condition

Analogously to the model presented by Reynolds et al. [2020], our formulation of the track capacity constraints is correct if and only if it is not possible for a train to violate the operational constraints single-handedly. We give conditions under which this is true below.

Definition 1. An antichain in a directed graph $G = (N, A)$ is a set $Z \subseteq A$ of arcs such that each path in G contains at most one arc in Z .

Definition 2. For two routes $r_1, r_2 \in N_r$, let

$$L(r_1, r_2) = \min \left\{ \sum_{r' \in p \setminus r_2} \min_{v=1,2} L_{r'}^v : p \text{ is an } r_1\text{-}r_2 \text{ path in } G_r \right\}$$

be a lower bound on the minimum total traversal time from r_1 up to but not including r_2 . For example, if $(r_1, r_2) \in A_r$ then $L(r_1, r_2) = \min\{L_{r_1}^1, L_{r_1}^2\}$.

Assumption 1. For each $(r, t) \in N_0$, $A_{r,t} \cap \bar{A}_{r,t} = \emptyset$ and $A_{r,t} \cup \bar{A}_{r,t}$ is an antichain in G .

Proposition 1. Assumption 1 is true if for each $r \in N_r$, either

(i) $S_r \cup \{r\}$ is an antichain in G_r , or

(ii) $L(r_1, r_2) \geq \max_v L_{r_1}^v + h_{r_1}$ for each pair $r_1, r_2 \in S_r \cup \{r\}$.

Proof. Let $(r, t) \in N_0$. Since $r \notin S_r$ by definition, $W_{r,t} \cap \bar{W}_{r,t} = \emptyset$ and hence $A_{r,t} \cap \bar{A}_{r,t} = \emptyset$.

Suppose for contradiction that at least one of (i) and (ii) holds, and that there is a *source-sink* path p in G that contains two distinct arcs $((r_0, t_0, w_0), (r_1, t_1, w_1))$ and $((r_2, t_2, w_2), (r_3, t_3, w_3))$ in $A_{r,t} \cup \bar{A}_{r,t}$, where without loss of generality $t_1 \leq t_3$. By the definitions of $A_{r,t}$ and $\bar{A}_{r,t}$, the routes r_1 and r_3 are in $S_r \cup \{r\}$. However, since $t_1 \leq t_3$, there must be a subpath q of p from (r_1, t_1, w_1) to (r_3, t_3, w_3) , and hence a path from r_1 to r_3 in G_r , contradicting (i). Furthermore,

$$\begin{aligned} t - (L_{r_1}^{w_1} + h_{r_1}) + 1 + L(r_1, r_3) &\leq t_1 + L(r_1, r_3) && (r_1, t_1, w_1) \in W_{r,t} \cup \bar{W}_{r,t} \\ &\leq t_3 && q \text{ must span at least } L(r_1, r_3) \text{ time intervals} \\ &\leq t. && (r_3, t_3, w_3) \in W_{r,t} \cup \bar{W}_{r,t} \end{aligned}$$

This rearranges to $L(r_1, r_3) \leq L_{r_1}^{w_1} + h_{r_1} - 1$, which contradicts (ii). Therefore neither (i) nor (ii) holds, and the result is proved by contradiction. \square

Note that the conditions of Proposition 1 can be checked much more easily than checking Assumption 1 directly. Condition (i) is satisfied for all routes in our instances for Derby station.

5.4 Objective Function and Arc Weights

507

The quality of a given solution to the TTRP is measured as the sum of the weights of the paths in the solution. A smaller sum corresponds to a better solution, so the problem is a minimisation problem. The weight of a given path for train k is the sum of the weights c_a^k of the arcs a that make up the path. These weights depend on both the arc and the particular train, so each arc a in G has a set of weights $\{c_a^k : k \in \mathcal{K}\}$.

508

509

510

511

512

The weights are selected such that the negative of the sum of the weights of the paths in a solution corresponds to the utility associated with the solution by Network Rail. This utility is modelled as the total weighted utility over all trains k and scheduled events j , given by

$$U = \sum_{k \in \mathcal{K}} \alpha_k \sum_{j=1}^{J^k} \beta_k^j U_k^j.$$

Train priorities and event priorities are controlled by parameters α_k and β_k^j , respectively. The set of events J_k for each train k includes all of its station stops and its exit from the modelled area. Each event j specifies both a route r_j^k and a time interval a_j^k in which the train should arrive into the route. The quantity U_k^j is the utility accrued by train k at stop j . It is equal to zero if train k does not visit r_j at all, and $\gamma(t - a_j^k) = \phi^{-\omega|t - a_j^k|}$ if train k enters r_j in time interval t (and hence $t - a_j^k$ time intervals late).

513

514

515

516

517

518

To facilitate the representation of this objective function, the weights c_a^k take the following values:

519

520

- $c_a^k = 0$ if $a \in A_2, A_3, A_5, A_6$ for all $k \in \mathcal{K}$. 521
- $c_a^k = \infty \mathbb{1}_{\{j \neq k\}}$ for all $k \in \mathcal{K}$ and $a = (source, (r_0^j, a_0^j, v_0^j)) \in A_1$. This ensures that trains begin in their initial position, rather than the initial position of a different train. 522
523
- Let $j \in J^k$ be a scheduled event for train $k \in \mathcal{K}$ that requires train k to arrive into route r_j^k at time interval a_j^k . Let $t \in \mathcal{T}$ be a time interval. Then: 524
525
 - If the event requires the train to stop at a platform, then all arcs $a \in A_4$ that enter node (r_j^k, t, v_0) have weight $c_a^k = -\alpha_k \beta_k^j \gamma(t - a_j^k)$. 526
527
 - If the event doesn't require the train to stop (e.g. passing a junction), then the weight $c_a^k = -\alpha_k \beta_k^j \gamma(t - a_j^k)$ applies to arcs in $a \in A_4$ that enter any of the nodes (r_j^k, t, v) where $v \in N_v^{r_j^k}$. 528
529
530
 - If the event has a departure time that is later than t , then all arcs $a \in A_4$ starting at 531

any of the nodes (r_j^k, t, v) , where $v \in N_v^{r_j^k}$, have $c_a^k = \infty$. This prevents train k from leaving r_j^k for another route before the scheduled departure time.

All other arcs $a \in A_4$ have weight $c_a^k = 0$ for each k .

Note that weights c_a^k with value ∞ ensure that an optimal solution will never contain a path for train k that contains arc a . In computations, a sufficiently large floating point value is used to represent ∞ .

5.5 MIP Formulation and Solution

Although the model presented in this paper differs from that presented by Reynolds et al. [2020], it can be formulated as a Mixed Integer Program analogously and therefore solved using the same branch-and-price algorithm. This is because the differences between the models are expressed in the definitions of both the graph G on which the problem is defined, and the sets $A_{r,t}$ and $\bar{A}_{r,t}$.

The formulation is a path-based flow formulation with binary variables $\lambda^{k,p}$ used to indicate which *source-sink* path $p \in P^k$ in the TST graph is selected for each train k . Thus, the formulation of the TTRP is given by

$$\min \sum_{k \in \mathcal{K}} \sum_{p \in P^k} \left(\sum_{a \in A} c_a^k x_a^{k,p} \right) \lambda^{k,p} \quad (2a)$$

$$\text{s.t.} \quad \sum_{k \in \mathcal{K}} \sum_{p \in P^k} \left(\sum_{a \in A_{r,t}} x_a^{k,p} + \delta \sum_{a \in \bar{A}_{r,t}} x_a^{k,p} \right) \lambda^{k,p} \leq 1 \quad \forall (r, t) \in N_r \times \mathcal{T} \quad (2b)$$

$$\sum_{p \in P^k} \lambda^{k,p} = 1 \quad \forall k \in \mathcal{K} \quad (2c)$$

$$\lambda^{k,p} \in \{0, 1\} \quad \forall k \in \mathcal{K}, p \in P^k, \quad (2d)$$

where $\delta > 0$ is a small positive constant, and each $x_a^{k,p}$ is a constant that is equal to 1 if path $p \in P^k$ for train k contains arc $a \in A$, and equal to 0 otherwise.

The objective (2a) is to minimise the total weight of all of the selected train paths. This corresponds to maximising Network Rail's utility. Constraint (2b) ensures that the track capacity constraints outlined in Section 5.2 are respected. For example, if a time-space resource (r, t) is occupied twice, then the left hand side of (2b) is 2, violating the constraint. Similarly, if (r, t)

is both occupied and banned, then the left hand side of (2b) is $1 + \delta$, which also violates the constraint. However, the constant δ is given a small value so that the resource can be banned multiple times without violating the constraint. In our instances, a value of $\delta = 0.05$ was sufficient to ensure that there was no practical constraint on the number of times a resource could be banned. Constraint (2c) ensures that exactly one path is selected for each train. Finally, constraint (2d) states that the variables are all binary.

This problem can be solved using the branch-and-price algorithm described by Reynolds et al. [2020]. Column generation is used to solve the LP relaxation at each node of the branch-and-bound tree. Variables are generated in each column generation iteration from the solution of one subproblem for each train. These subproblems are shortest-path problems on G , which is a directed acyclic graph. Both partial pricing and reduced cost variable fixing are used as column generation acceleration strategies. A customised branching rule is used that branches on conflicts between pairs of trains over resources (r, t) in the track capacity constraints.

6 Computational Study

A computational study has been carried out to compare two models:

(FS) The fixed-speed model proposed by Reynolds et al. [2020], with traversal times calculated using Method 1 (see Section 4.1).

(VS) The variable-speed model proposed in this paper, with traversal times calculated using the transition-based Method 3 (see Section 4.3).

Section 6.1 describes the new set of instances for Derby station in the UK that is used for our computational study. Section 6.2 compares the traversal times produced by the different estimation methods. Finally, Section 6.3 evaluates the performance of the branch-and-price solution algorithm for the two models. Full tables of results are available online (see [Reynolds, 2020]).

Traversal time estimation methods were implemented in the Python 3.6 language, using the package Scikit-learn 0.20.3 [Pedregosa et al., 2011] for fitting Gaussian mixture models, and the package SciPy 1.2.1 [Virtanen, 2020] for performing Mood’s test. The branch-and-price algorithm is implemented using SCIP 6.0.2 [Gleixner et al., 2018] as a branch-and-price framework. Custom plugins for SCIP are written in the C language, and Gurobi 9.0 [Gurobi Optimization LLC, 2020] is used as the linear programming solver. The experiments were carried out on a computing node equipped with an 18 core Intel Xeon E5-2699 v3 CPU with 2.30GHz and

500GB of RAM, running Ubuntu 16.04.

587

6.1 Instance Data

588

A new set of 310 instances has been created for the computational study. These instances are based on real data from an area of railway centred around Derby station in the UK. Derby station lies on both the Midland Main Line and the Cross Country Route, two heavily used, double-track, inter-city lines connecting London with Leeds, and Bristol with York via Birmingham, respectively. The station also hosts local services to Nottingham and Matlock. In 2018–2019, Derby station had 3,902,000 passenger entries and exits and 619,000 passenger interchanges. Lying at the confluence of several lines, Derby Station is regarded as a traffic bottleneck. This makes it suitable for testing our model.

589

590

591

592

593

594

595

596

The area modelled is shown in Figure 12. Derby station has 6 bidirectional platforms and 204 track circuits. The area as a whole contains portions of three double track lines, and consists of 142 routes in total, with 228 valid berth transitions. The area includes five small stations in addition to Derby: Spondon, Peartree, Duffield, Belper and Ambergate.

597

598

599

600

Each one of the 310 instances covers a different hour long period. Ten instances, covering between 8am and 6pm, are used from each of the 31 days in January 2020. They were created using real timetables, and real data about traffic perturbations. The level of traffic perturbation varies considerably between the instances. However, they provide a representative sample of traffic conditions at Derby over January 2020.

601

602

603

604

605

The number of trains in each instance is shown as a histogram in Figure 13. The most common number of trains is 19, whilst the largest number is 23. The number of *conflicts* in each instance for both (FS) and (VS) is shown in Figure 14. This is defined as the number of track capacity constraints that are violated by the solution obtained from solving each model without any track capacity constraints. The number of conflicts in a given instance can be different for models (FS) and (VS) because the differing traversal times result in trains reaching different parts of the track at different times. Nevertheless, we see that there is a strong positive relationship because although the models and traversal times differ, the TTRP instances used are identical. Table 1 compares the number of *train pair conflicts* in the instances when using (FS) and (VS). This is the number of unique train pairs involved in at least one conflict together. Measuring train pair conflicts can be more informative than measuring conflicts. This is because each train pair can only have at most one train pair conflict, where several conflicts can occur for the same train pair in consecutive time intervals over the same route. Both the number of

conflicts and the number of train pair conflicts have been shown by Reynolds et al. [2020] to be 619
 correlated with the number of branch-and-bound nodes required to solve instances to optimality. 620
 Discrepancies between (FS) and (VS) can therefore cause differences in the performance of the 621
 solution algorithm. 622

6.2 Traversal Time Estimation

623

Historical Train Describer data was used to estimate traversal times for routes in Derby station using Method 3 (see Section 4.3). The application of Method 3 identified that 15 out of the 140 routes required two different traversal times for (VS). For these 15 routes, sufficient evidence was found for a difference of at least one time interval between the traversal times of speed profile types v_1 and v_2 — sufficient evidence was not found for the remainder of the routes. This shows that our statistical method requires a high standard of evidence for using two traversal times for a route. The effect of this is that nodes of speed profile type v_2 in the TST graph are included sparingly, resulting in a parsimonious optimisation model. Including two traversal times for a route introduces additional complexity and increases the size of the model, so it is important to do this only where it can be shown statistically to be most important.

633

The routes with two traversal times are highlighted in red in Figure 12. Some of these routes are adjacent to routes that frequently have conflicts, such as the routes entering platform 3 (the third platform from the top in Figure 12) at Derby station. This is likely to arise from the fact that some trains stop in preceding routes as a result of conflicts, whilst others do not — affecting the speed at which they traverse the route. Other routes with two traversal times are adjacent to stations at which only some trains stop, such as Peartree, Duffield and Belper. Trains that stop at these stations must decelerate or accelerate through adjacent routes, whilst trains that don't can continue at the line speed. These patterns conform to our expectations and therefore give us confidence that the traversal time estimation method is performing well.

640
641
642

The traversal times of routes that have three speed profile types (i.e. two traversal times) in the (VS) model (using Method 3) are shown in Figure 15 alongside the corresponding traversal times for (FS) (which uses Method 1). It shows that traversal times in (FS) are often similar to or the same as for traversal type v_2 for (VS). This is because the smallest cluster mean for each route is used as the traversal time in (FS), and the observations in that cluster overlap strongly with observations that are categorised as type v_2 in (VS). Whilst the difference between traversal times for v_1 and v_2 in (VS) is not large for most routes, even a single time interval (10 seconds) difference can be enough to affect the optimal rescheduled timetable. An exception to this is the traversal times $L_r^1 = 12$ and $L_r^2 = 6$ for route $r = \text{DY551_DC5108}$, which differ by a whole minute. This is a relatively long route on the open line in which trains stopping at Duffield station and trains not stopping there are likely to be travelling at very different speeds.

6.3 Algorithmic Performance

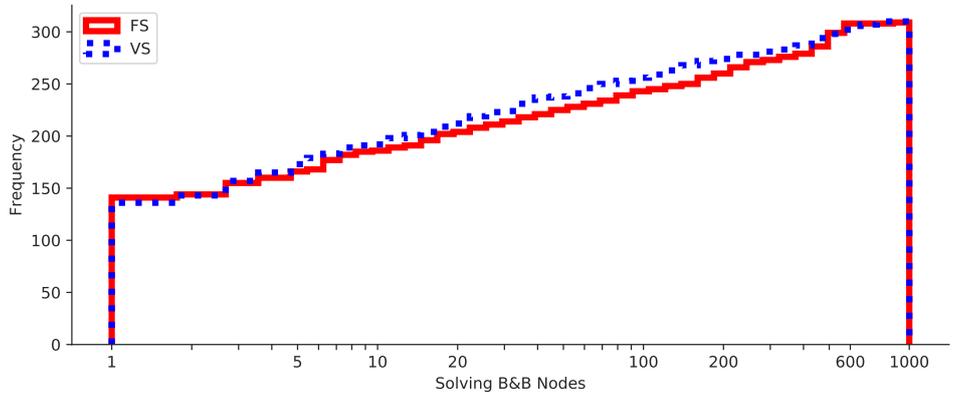

655

To understand how our branch-and-price algorithm performs when solving both models (FS) 656 and (VS), each of the real instances from Derby station were solved with a time limit of 600 657 seconds. Within this time limit, 282 of the 310 instances were solved to optimality with (FS), 658 and 287 were solved to optimality with (VS). This is a good result because it means that all 659 but the most difficult instances can be solved to optimality with the more accurate (VS). The 660 solving times of the instances that could be solved to optimality are shown in Figure 16(a) (note 661 that the x -axis is logarithmic with base 2). This figure demonstrates that the distribution of 662 solving times over the instance set are very similar for (FS) and (VS). However, the higher blue 663 line indicates that (VS) has a better solving performance than (FS) among models that took 664 over 100 seconds to solve. Specifically, the average solving times for all solved instances are 665 43.67 and 53.69 seconds for (VS) and (FS) respectively. 666

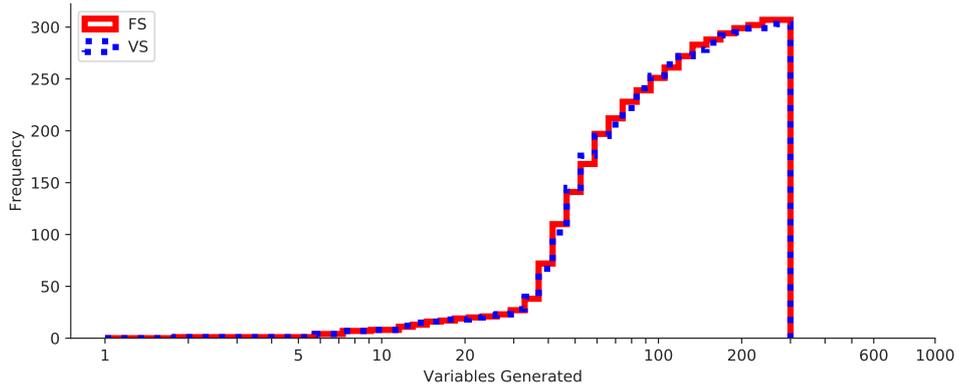

The explanation for the better performance of (VS) on difficult instances can be seen by study- 667 ing Figures 16(b) and 16(c). These show the number of branch-and-bound nodes explored, and 668 the number of variables (columns) generated, respectively, during the solving process. Figure 669 16(c) shows that the number of columns generated was almost identical, indicating that con- 670 vergence of the column generation algorithm for solving LP relaxations was not affected by 671 differences between (FS) and (VS). On the other hand, Figure 16(b) shows that there are more 672 instances with a smaller number of branch-and-bound nodes for (VS) compared to (FS). This 673

(a) Solution time (seconds)

(b) Number of branch-and-bound nodes

(c) Number of variables generated

Figure 16: Cumulative histograms comparing (FS) and (VS) over the set of instances with a time limit of 600 seconds. Note the x-axis is log-scaled.

is particularly evident for instances requiring between 20 and 600 nodes. Further, it is observed that across the complete set of instances (FS) required an average of 92.5 branch-and-bound nodes compared to an average of 76.04 for (VS). This difference in the number of branch-and-bound nodes is the likely to be the reason for the better solution times for (VS) on difficult instances. It is conjectured that this result arises from the difference in the quantity and quality of conflicts due to using more accurate traversal times in (VS) compared to (FS).

Both of the models were also evaluated using a time limit of 20 seconds. This reflects the short amount of time that is typically available for solving TTRP instances in practical, real-time environments. Of the 310 instances, 174 were solved to optimality by both models within this time limit. The optimality gaps for the remaining 136 instances are plotted in Figure 17. It shows that with both (FS) and (VS), high-quality solutions that are provably within 10% of optimality were found for the vast majority of instances. For each, only two instances had remaining optimality gaps exceeding 20%. This reinforces the evidence found by Reynolds et al. [2020], using instances for a different station, that the developed algorithm is suitable for real-time operations. Figure 17 also shows that whilst the distribution of remaining optimality gaps is similar for (FS) and (VS), (VS) has a larger concentration of instances with very small gaps. This corroborates our observation of better performance for (VS) when the time limit was 600 seconds.

Based on the results presented, we conclude that the benefits of variable speed modelling in (VS) compared with fixed speed modelling in (FS) come at no price for computational performance. This striking result highlights the value of applying a data-driven approach for improving the accuracy of the TTRP.

7 Conclusion

696

In this paper, we present a new variable-speed model for the TTRP that uses a time-space-type graph to approximate train speed profiles. To achieve this, the notion of a discrete speed profile type is introduced, and techniques for estimating traversal times based on historical Train Describer data are developed.

Our approach is tested using a new set of real instances for Derby station in the UK. These tests show that our data-driven approach results in a parsimonious model that is able to improve speed profile modelling relative to fixed-speed models in parts of the track network. In addition, these modelling enhancements come at no cost, in the sense that they do not lead to longer solving times in comparison with the fixed-speed model of Reynolds et al. [2020]. This represents a major contribution to modelling approaches for the variable speed TTRP.

Further work is needed to quantify the inaccuracies that still remain in speed profile modelling. For example, a simulation study using a microscopic railway simulator could be used to evaluate solutions produced by our model and compare them to solutions produced by different variable speed models. Our data-driven modelling approach also creates exciting opportunities to improve the statistical methodology for estimating traversal times based on speed profile types. One possibility is to use a Hidden Markov Model (see [Zucchini et al., 2016] for an introduction), in which speed profile types are the ‘hidden’ states, and traversal times are the observed data. This could open up the possibility of fitting mixture models for each route (as in Method 2) whilst additionally using the full transition data.
